(1942, pp. 484-500). On the basis of the experimental evidence McGeoch was led to question the general validity of the perseveration hypothesis and to favor a transfer theory of retroactive inhibition.

The main arguments advanced against the perseveration hypothesis were the following: (1) While perseveration of the neural activity after the end of learning is generally assumed to be limited to a period not exceeding a few minutes, interpolated activities introduced after hours or days are known to produce significant interference effects (for a review of the early evidence on this question see Britt, 1936, and Swenson, 1941). (2) There is no apparent support for the prediction implied by the perseveration hypothesis that the amount of interference should vary directly with the intensity of the interpolated activity (McGeoch, 1931). (3) The fact that intertask similarity is a major determinant of retroactive inhibition is at variance with the hypothesis and is clearly seen as constituting the most damaging objection to it. (4) Finally, the hypothesis cannot be reasonably extended to provide an explanation of the phenomenon of proactive inhibition. In light of these considerations the disruption of perseveration could not be accepted as the basic mechanism of interference; McGeoch left open the possibility, however, that such a mechanism may play some role in forgetting, for example, in producing retention losses in the absence of an interfering activity.

McGeoch viewed the demonstrated dependence of retroactive inhibition on intertask similarity as supporting the interpretation of interference at recall as a special case of negative transfer. As a matter of definition, since retroactive inhibition reflects an interaction between the effects of successive learning activities, it must be classified as a phenomenon of transfer. The operative conditions of retroaction can be subsumed under a general principle of negative transfer, namely, that the attachment of different responses to identical or similar stimuli creates conditions of interference. The reference paradigm is therefore *A-B, A-D, A-B*. During the second stage elicitation of the competing response *B* retards the establishment of the association *A-D* (associative inhibition). In the third stage, when the first association is to be recalled, elicitation of the recently acquired competing response *D* inhibits the reproduction of *B*. The interpretation of retroactive inhibition as a special case of negative transfer thus takes the form of a theory of *reproductive inhibition.* That is, retroactive inhibition is interpreted as reflecting the competition of responses at the time of recall: the reproduction of *B* is inhibited by the recall of *D*. "Responses thus inhibited are not necessarily lost from the subject's repertoire, but are kept by other responses from appearing" (McGeoch, 1942, p. 495). Thus, the *test of recall* is identified as the temporal locus of the retroactive effects. (For earlier statements of the theory in the context of experimental studies see McGeoch, 1936; McGeoch, McKinney, & Peters, 1937.) The implications of Gibson's generalization hypothesis for retroactive inhibition are equivalent to this position in all essential respects.

In developing his account of retroaction, McGeoch cited the occurrence of interlist intrusions at recall (substitution of *D* for *B*) as direct evidence of response competition. He acknowledged that overt intrusions account for only a fraction of the decrement in recall but considered it likely that many such errors remain implicit. That is, subjects recognize the intrusions as inappropriate and withhold them. Moreover, competing implicit tendencies may block each other so that there may be reproductive inhibition in the absence of either overt or reportable intrusions (see McKinney & McGeoch, 1935).

The theory of reproductive inhibition comprises two major hypotheses that should be clearly distinguished from each other even though they are closely linked in McGeoch's formulation. First, it is asserted that the availability of the original associations is not reduced by interpolated learning; the old

system of responses remains intact while the new one is being acquired. This assumption has been designated the independence hypothesis (Barnes & Underwood, 1959). Second, competition between alternative responses inhibits recall. One response may be displaced by another that is momentarily dominant, or implicit responses may block each other. This is the hypothesis of response competition, or reproductive inhibition proper, which specified the mechanism of interference *at the time of recall.* The two hypotheses need not necessarily be linked together, and it is possible to reject one and to retain the other (see Postman, 1961a). In particular, even if the independence hypothesis is shown to be false, competition at recall may still be responsible for the loss of responses that have remained available. That is precisely the position which gained wide acceptance as a result of subsequent developments.
Figure 21.24. Two-factor theory of retroactive inhibition. The empirical function (solid line) shows the amount of retroactive inhibition as a function of the degree of interpolated learning. The two theoretical curves (dashed lines) represent estimates of the relative weights of two factors in determining the observed retention losses. The interference attributable to competition of responses is taken as two times the average frequency of interlist intrusions on the recall trial. The obtained frequency is multiplied by two to take account of intrusions of parts of syllables that could not be included in the count. The curve for factor *X* represents losses not attributable to response competition. Factor *X* was tentatively identified as the unlearning or extinction of the original responses during interpolated learning. (Melton & Irwin, 1940.)

Two-factor theory The independence hypothesis was called into question in a classical paper by Melton and Irwin (1940) who proposed a two-factor theory in place of McGeoch's single-factor interpretation. The two-factor theory was formulated on the basis of the results of an experiment which investigated retroactive inhibition as a function of the degree of interpolated learning. Serial lists of 18 nonsense syllables were used as the learning materials. There were five trials of original learning followed by either 0, 5, 10, 20 or 40 trials of interpolated learning. The original list was relearned to a criterion of two perfect recitations at the end of the 30-minute retention interval. The absolute amount of retroactive inhibition at recall was a negatively accelerated increasing function of the degree of interpolated learning (Figure 21.24). Note that there is actually a slight inversion in the function after 40 interpolated trials; dissipation of the interference during relearning was also found to be most rapid for that condition. Interlist intrusions, which could be attributed to either the similarity of the serial positions or the formal similarity of the intruding and the displaced syllables, accounted for only a small percentage of the observed retention losses. More important, the functions relating the amount of retroactive inhibition and the frequency of intrusions to the degree of interpolated learning did not coincide. As Figure 21.24 shows, the number of intrusions rose to a maximum after 10 trials of interpolation and declined thereafter, even though retroactive losses continued to increase.

If the frequency of interlist intrusions is taken as an index of reproductive inhibition, it appears that there is some other determinant of interference that carries progressively greater weight as the degree of interpolated learning increases. Melton and Irwin labeled

this factor "X" and tentatively identified it as the unlearning of the first-list associations during interpolated practice. Responses from the original list that occur as overt or implicit intrusions during interpolated learning fail to be reinforced and are weakened. Thus unlearning is conceived to be a process akin to extinction. Responses that have been unlearned are not available at the time of recall. The function for factor *X* indicates that the amount of unlearning increases with the number of interpolated trials. The rapid dissipation of interference at the highest level of interpolation suggests that unlearned responses can be relearned with considerable saving.

The major innovation introduced by the two-factor theory is the assumption that the processes responsible for retroactive inhibition have a dual locus: as interpolated learning proceeds, an increasing number of the original responses are unlearned and thus become unavailable; those which remain available are subject to competition from interpolated responses at the time of recall. The relative amount of retention loss attributable to reproductive inhibition is maximal when the competing response systems are at or near equal strength.

List differentiation The two-factor theory represented an important alternative to the view that all of the retention losses produced by interpolated learning are the result of reproductive inhibition. The lack of correlation between the frequency of overt intrusions and the absolute amount of retroactive inhibition does not, however, necessarily imply the operation of a factor other than reproductive inhibition. This argument was developed by Thune and Underwood (1943) who carried out an experiment paralleling that of Melton and Irwin but with paired adjectives as the learning materials. In their study, five trials of original learning were followed by either 0, 2, 5, 10, or 20 trials of interpolation. Whereas the amount of retroactive inhibition described the usual negatively accelerated increasing function, the frequency of overt intrusions reached a maximum after 10 trials and declined sharply after 20 trials. Thus the lack of a one-to-one relation between the frequency of intrusions and total retention losses was confirmed. As the investigators pointed out, however, the discrepancy between the two indices of interference may be attributed to systematic changes in the ratio of overt to covert intrusions. This ratio is highest when the strength of the interpolated responses just exceeds that of the original ones. As the difference in favor of the interpolated responses increases further, subjects are more and more likely to recognize intrusion errors as inappropriate and to reject them.

The extent to which competition becomes overt thus can be seen to depend on the subject's ability to identify the list membership of responses; in principle, the amount of retention loss may be influenced as well if the rejection of implicit errors occurs with sufficient speed to permit the substitution of the correct responses. These assumptions were expressed by Underwood (1945) in the form of the hypothesis that the amount and characteristics of retroactive inhibition will be a function not only of the strength of the interpolated responses but also of the degree of list differentiation. At a given level of original learning, list differentiation is an increasing function of the degree of interpolated learning; that is, it reflects the relative strength of the latter. Subsequently Underwood (1949) added the assumption that differentiation also increases with the absolute strengths of the competing response systems. The degree of differentiation will also vary inversely with the length of the time interval between the end of interpolated learning and the test of recall.

The concept of differentiation has been used widely in the interpretation of the characteristics of performance under conditions of interference, and in particular has been invoked to account for variations in the frequency of overt intrusions. For a long time

it remained entirely a theoretical construct. Recently, however, Winograd (1968) carried out a series of experiments in which the effects of variables assumed to influence list differentiation were evaluated directly. The basic procedure consisted of the presentation of two successive lists of words followed by a test of differentiation. During the test the two sets of items were shown in a mixed order and the subjects were required to identify the list membership of each. The expected functional relations were observed. Accuracy of list identification was found to be (1) poorer when the frequency of presentations for the two lists was the same than when it differed, (2) more accurate as the absolute frequency of presentations of the two lists was increased, and (3) a decreasing function of the length of the retention interval. It should be noted that the subjects were required to identify the list membership of all items. Recall was not measured, but presumably some items would not have been available, especially on the delayed test. As the author points out, in the application of these findings to phenomena of interference the question remains open of whether loss of differentiation leads to forgetting by increasing response competition or forgetting results in a loss of differentiation. It is also possible that the two processes develop at somewhat independent rates. Thus, Deese and Marder (1957) found that after the acquisition of two serial lists of synonymous adjectives the amount of first-list retention remained essentially constant over a 24-hour period, whereas the frequency of interlist intrusions increased progressively. List differentiation declined more rapidly, therefore, than did recall of the original material.

While the relation between list differentiation and recall remains to be clarified, the available evidence is consistent with the assumption that the overt manifestation of competition, that is, the occurrence of interlist intrusions, is significantly influenced by the subject's ability to identify the list membership of responses. The lack of a consistent relation between intrusions and amount of retroactive inhibition does not, therefore, in itself support the inference that first-list associations are unlearned.

Specific versus generalized response competition Before we turn to a detailed consideration of the hypothesis of unlearning, the factor of competition requires some further discussion. The competition to which McGeoch referred, and which is one of the two sources of interference in the formulation of Melton and Irwin, is a consequence of the successive attachment of different responses to the same stimulus. At the time of recall both responses may be aroused and block each other; or one of the responses may be momentarily dominant and displace the other. With the strength of individual associations fluctuating from moment to moment, the effects of competition are likely to be transitory; given sufficient time, the subject should be able to produce both responses. Since the interference is between the responses to an individual stimulus, the competition may be designated as specific. The extent to which specific competition results in overt intrusions will presumably depend on the degree of list differentiation.

There is evidence pointing to another form of competition that results from the subject's tendency to continue giving responses from the list he practiced last. Thus, when a test of recall is administered immediately after the end of interpolated learning, the persisting dominance of the second-list repertoire will interfere with the recall of responses from the first list. This mechanism of interference has been designated generalized competition by Newton and Wickens (1956). While generalized and specific competition may shade into each other, the conceptual distinction between them is important; the former refers to the dominance of a response repertoire, the latter to the arousal of an interfering response to an individual stimulus. Generalized competition is not likely to result in many overt interlist intrusions. The dominant
Figure 21.25. Unlearning of first-list associations during second-list learning. The successive lists conformed to the *A–B, A–D* paradigm. Retention was tested by the MMFR method; that is, subjects recalled both the first-list and the second-list responses. Changes in performance as a function of the number of trials on the second list are shown. Scores are based on the numbers of responses given to the appropriate stimulus and identified correctly as to list membership. (Barnes & Underwood, 1959.)

fined in the original statement of the two-factor theory.

In the experiment by Barnes and Underwood the learning materials were lists of eight paired associates, with trigrams as stimuli and adjectives as responses. Two paradigms of transfer were compared, namely, *A–B, A–D* and *A–B, A–B′* (synonymous responses). Original learning was to a criterion of one perfect recitation, followed by either 1, 5, 10, or 20 trials of interpolated learning. The results of the MMFR tests for the *A–B, A–D* paradigm are shown in Figure 21.25. The number of first-list responses recalled declines steadily as the number of interpolated trials is increased. Second-list recall becomes, of course, progressively higher. When both responses were recalled, items from the second list tended to be given first. The large majority of the available responses were given to the correct stimuli. At the end of recall the list membership of the responses was identified with a high degree of accuracy; that is, there was little loss of differentiation on the test immediately after the end of interpolated learning. The results support the conclusion that first-list associations are unlearned or extinguished during the acquisition of the second list. Unlearning appears to account for virtually all of the observed retroactive inhibition.

The picture is quite different for the *A–B, A–B′* paradigm. Acquisition of the second list was extremely rapid, recall being nearly perfect after one learning trial. Increases in retroactive inhibition were extremely slow, with a loss of less than one item at the highest level of interpolated learning. As was indicated earlier, these findings strongly point to mediational chaining (*A–B–B′*) during second-list learning. As a consequence, the first-list associations continue to be reinforced during the interpolated trials. The fact that *B* tends to be recalled before *B′* and the subjects' reports are in agreement with this interpretation. The retroactive effects that were observed may be attributed to occasional failures on the part of the subjects to recognize the similarity relation between successive responses, in which case the paradigm reduced to *A–B, A–D*. In addition, it is possible that the mediator ceases to be functionally useful late in interpolated learning when a strong direct association between the stimulus and the response has been established; at this stage the mediator may begin to be unlearned. The difference between the *A–D* and *A–B′* paradigms is obtained with mixed as well as unmixed lists (Postman, 1962b).

The finding of Barnes and Underwood that under conditions of negative transfer there is a substantial reduction in the availability of first-list associations after interpolated learning has been confirmed in many subsequent investigations. The phenomenon of

TABLE 21.5

	Forward associations	*Backward associations*	*Contextual associations*
A–B, C–D	no	no	yes
A–B, C–B	no	yes	no
A–B, A–D	yes	no	yes
A–B, A–Br	yes	yes	no

unlearning is, therefore, firmly established, at least to the extent that the retention losses observed on the MMFR test reflect the operation of this process. The major questions of interpretation on which subsequent analyses have centered are (1) what is unlearned, and (2) what is the exact mechanism responsible for unlearning.

Conditions and Characteristics of Unlearning

A component analysis of unlearning A widely accepted answer to the question of what is unlearned is provided in an analysis by McGovern (1964) who identified three classes of associations which are subject to unlearning: (1) forward associations, (2) backward associations, and (3) contextual associations. We shall refer to the first two, which link individual stimuli and responses, as specific associations. Contextual associations refer to connections between the responses and the environmental situation, for example, the cues provided by the room, the experimental equipment, and so on. Response recall, as distinct from associative learning, depends on the development of contextual associations. It is McGovern's thesis that each of these component associations is subject to unlearning whenever the *A–B, A–D* paradigm obtains for these associations in the successive lists. On the basis of this assumption it is possible to specify exactly which associative components will be unlearned under various paradigms of transfer. Table 21.5 summarizes the application of this analysis to the conditions considered by McGovern in her experiment. Two major predictions are implied. First, unlearning should be greater for *A–D* and *A–Br* than for *C–D* and *C–B* because the former paradigms entail an extinctive relation for two components, and the latter for only one. Second, if the requirement of response recall is removed on the retention test by making the responses available and instructing the subject to match them with the appropriate stimuli, there should be a substantial amount of improvement only for those cases in which contextual associations are assumed to be lost (*C–D* and *A–D*).

The learning materials in McGovern's experiment were lists of eight paired associates, with nonsense syllables as stimuli and adjectives as responses. (Because of the use of nonsense syllables as stimuli the results for the *C–D* and *C–B* paradigms must be interpreted with caution; see page 1061.) The first list was learned to a criterion of one perfect recitation; there were 15 trials on the second list. Retention of the first list was tested either by an unpaced test of recall or by associative matching. Only the former test was administered under the rest condition. The mean numbers of correct responses were as follows:

	C–D	C–B	A–D	A–Br	*Rest*
Recall	6.54	6.42	4.79	4.75	7.71
Matching	7.83	6.87	6.54	5.58	—

It can be seen that the major predictions are confirmed. On the test of recall the losses are greater for *A–D* and *A–Br* than for *C–D* and *C–B*. The differences between recall and matching are greatest for *C–D* and *A–D*. The decline for *C–D* is taken to reflect directly the extinction of contextual associations.

Note that, with the exception of *A–Br*, the decrements on the matching test are relatively small, that is, of the order of one item. It appears that the unlearning of contextual associations proceeds more rapidly than that of specific ones.

A complementary experiment demonstrating the extinction of backward associations was reported by Keppel and Underwood (1962a). The materials and procedure were the same as in McGovern's experiment, except that recall of backward associations was required on the test of retention. That is, the response terms were provided, and the subjects had to recall the stimuli with which they had been paired. The mean numbers of correct responses were:

C–D	C–B	A–D	A–Br	*Rest*
4.60	1.85	5.05	3.40	5.80

As the authors recognize, the results for the *A–D* and *A–Br* paradigms cannot be interpreted unequivocally since under these conditions the stimulus terms to be recalled on the test received continued exposure during interpolated learning. Nevertheless the pattern of results clearly indicates extinction of backward associations. In agreement with McGovern's analysis, the paradigms for which extinction of backward associations is expected show the greatest losses. The critical comparisons that isolate this factor are between *C–D* and *C–B*, and between *A–D* and *A–Br*. Subsequent studies, in which both nonsense syllables and meaningful words were used as stimulus (*A* and *C*) terms, have consistently yielded evidence for the unlearning of backward associations under the *C–B* paradigm (Ellington & Kausler, 1965; Greenbloom & Kimble, 1965; Houston, 1966c).

When successive lists conform to the *A–B, C–B* paradigm, unlearning of both forward and backward associations has been observed. Greenbloom and Kimble (1965) carried out tests in both directions within the same design and confirmed this conclusion, with the backward losses considerably larger. The backward associations are in conflict with each other, and to the extent that *B–A* is activated during second-list learning it may be expected to be unlearned. It is less clear, however, why there should also be a reduction in forward recall. McGovern considers two ways in which backward associations may aid forward recall: they may serve a checking function (we considered earlier the description of such a process by Twedt and Underwood, 1959), or they may serve to mediate forward associations when the latter have been weakened. Elimination of these sources of facilitation would lead to decrements in *A–B* recall. An alternative interpretation is that unlearning is in principle bidirectional: backward strength is lost whenever the forward association is weakened, and vice versa. Such an assumption would follow from the principle of associative symmetry (Asch & Ebenholtz, 1962) according to which the forward and the backward strengths of an association are always strictly equivalent; apparent differences in performance are attributed to the differential availability of the terms to be recalled, the items used as responses during training being more available.

There is other evidence that after unlearning has presumably occurred in one direction, there is interference with recall in the other direction as well. Using highly familiar stimulus terms (numbers) in an attempt to minimize the problem of continued exposure to the stimuli during interpolation, Houston (1964b) found significant unlearning of backward associations for the *A–B, A–D* paradigm. In an experiment by Birnbaum (1966) the acquisition of the original list was bidirectional; that is, subjects were given equal amounts of practice on *A–B* and *B–A*. Interpolated learning was in one direction only; however, the losses observed on the test of recall were essentially symmetrical. She concluded that associations are unlearned equally in both directions. The conclusion is probably premature, however, since it is quite

TABLE 21.6

	Rest	C–D	C–B	A–D	A–Br	A–B′
Recall	9.7	9.0	8.5	4.7	6.2	7.1
Multiple choice	9.6	9.6	8.4	8.9	6.5	8.4

possible that the habit of bidirectional practice was carried over from original to interpolated learning. In any event, it is hazardous to generalize from her results to those obtained under standard conditions (Keppel, 1968, pp. 178f.). Somewhat more convincing is the finding of Cheung and Goulet (1968) that the amount of backward unlearning is essentially equal for the *A–B, C–B* and *A–B, B–*C paradigms. In the former case the extinctive relation obtains between successive backward associations, in the latter between first-list backward and second-list forward associations.

Differential unlearning of contextual and specific associations In the discussion of McGovern's results it was noted that the amount of unlearning attributable to the loss of specific associations, as indexed by the matching test, was in general relatively low. Subsequent studies in which the same or a closely similar testing procedure and comparable degrees of original learning were used have yielded comparable results (Garskof & Sandak, 1964; Postman, 1965; Sandak & Garskof, 1967; Garskof, 1968). In the case of the *A–B, A–D* paradigm the associative losses appear to be of a considerably smaller order of magnitude than those attributable to the unlearning of contextual associations. In these studies, however, as well as in McGovern's, response recall was required during the acquisition of the lists. Comparisons (either within or between experiments) of the results obtained on recall and on matching tests are, therefore, not conclusive, for two main reasons. First, with respect to the requirements of the retention task, degree of learning may well be appreciably higher when a test of associative matching rather than of recall is used. On this basis a difference in favor of the former would be expected. Second, the methods of acquisition and of testing are more nearly continuous for recall than for matching; for the latter the shift in the mode of responding may have an adverse effect on performance. The resulting decrement is likely to be greater for an experimental group which has had more acquisition trials than the control group; the interval between the end of practice and the retention test is also shorter for the experimental group. These difficulties are largely avoided when the same method is used in the acquisition and in the test stage, recall or matching as the case may be, with degree of learning equated as closely as possible. An attempt to meet these requirements was made in the study by Postman and Stark (1969) mentioned earlier (p. 1066) in which the recall and multiple-choice methods were compared under various paradigms of transfer. An unpaced test of first-list retention was given at the end of interpolated learning which permitted an evaluation of the amounts of retroactive inhibition relative to appropriate rest groups. The test scores are shown in Table 21.6 (with the multiple-choice measures corrected for guessing).

On the test of recall the amount of retroactive inhibition varies widely, with the differences among paradigms showing a characteristic pattern. The retention loss is greatest for *A–D*. By contrast, the decrements on the multiple-choice test are quite small, and there is significant retroactive inhibition only for *A–Br*. The loss for *A–D* is now negligible. Two additional test trials were given to all groups. In spite of the absence of feedback there was an upward trend in the scores (see Richardson & Gropper, 1964). On the final multiple-choice trial retroactive inhibition was entirely eliminated

for all paradigms except *A–Br*. While the recall scores also increased, the level of retroaction remained substantial.

Taken together, the available evidence indicates that specific associations are highly resistant to interference. The results of the study considered last indicate that there is an appreciable amount of associative unlearning only under conditions of heavy and persistent negative transfer, that is, *A–Br*. Thus, it appears that unlearning is in large measure a matter of reduced response availability. These findings bear directly on the question of the mechanism of unlearning to which we turn next.

The mechanism of unlearning: the elicitation hypothesis In the formulation of the two-factor theory an analogy was suggested between unlearning and the extinction of conditioned responses. First-list responses elicited during interpolated learning fail to be reinforced or are "punished" and thus are extinguished. The more precise analogy is to counterconditioning since a new response to the old stimulus is reinforced. In any event, according to this interpretation, elicitation of old responses as errors is an essential condition of extinction. A correlation would have to be expected between the frequency with which first-list responses occur as errors and the likelihood of their being unlearned (Melton, 1961). When overt intrusions are used to gauge the frequency of errors, such a correlation is not obtained. For example, Keppel and Rauch (1966) produced substantial variations in the number of interlist intrusions without influencing the amount of unlearning. However, such findings do not necessarily entail the rejection of the elicitation hypothesis because it has always been recognized that the large majority of intrusions are likely to remain covert. Conditions that encourage a high error rate may merely raise the ratio of overt to covert intrusions. This point continues to be missed by investigators who attempt to use the frequency of overt interlist intrusions as an index of the opportunities for extinction (for example, Paul & Silverstein, 1968).

An alternative approach is to compare conditions of unlearning in which the total frequency of unreinforced elicitations, both overt and covert, may be assumed to vary, essentially on a priori grounds. Unreinforced elicitation is treated as an intervening construct, and the results of any one experiment do not provide conclusive evidence for the efficacy of this mechanism. The cumulative findings may, however, permit an evaluation of the heuristic value of the hypothesis. A study by Postman, Keppel, and Stark (1965) took its point of departure from the assumption that the frequency of unreinforced elicitations of first-list responses during interpolated learning should be greater when the class of responses (letters or adjectives) in the *A–B* and the *A–D* list remains the same than when it changes. As expected, significantly more unlearning was found under the former than under the latter condition (see also Friedman & Reynolds, 1967).

Entirely different operations were used by Goggin (1967) in an attempt to influence the frequency of unreinforced elicitations. In her experiment the first list (*A–B*) was learned by the prompting method; that is, the appropriate pair was always exposed just before the subject had to recall the response to a given stimulus. Under these circumstances errors on acquisition trials are extremely unlikely. The second list was learned either by the prompting method or by the anticipation method; the latter is, of course, conducive to interlist as well as intralist errors. It was assumed that interpolated learning under the prompting procedure would minimize the unreinforced elicitation of first-list responses. In accord with prediction, there was significantly less unlearning when the second list was learned by the prompting rather than the anticipation method. This result was obtained in spite of the fact that the similarity of context during original and during interpolated learning must have been greater when the method remained the same (prompting in

both stages) than when it changed (prompting followed by anticipation).

Finally, the elicitation hypothesis provides one possible explanation of the increase in retroactive inhibition with the number of interpolated lists (Postman, 1965). When there is a fixed period of interpolated learning, the level of dominance of the new responses over the old responses should vary inversely with the number of different lists practiced during this period. That is, the larger the number of lists, the weaker the several interpolated associations will remain relative to the original ones and the longer should the latter continue to be elicited as intruding errors. Moreover, as Birnbaum (1968) has suggested, quite apart from the developing differences in strength between original and interpolated habits, the introduction of each new list may serve as a "disinhibitor" conducive to the reactivation of the original associations.

It is clear that the evidence in support of the elicitation hypothesis remains highly circumstantial. Even if the available data are viewed as consistent with the hypothesis, the question remains of whether unreinforced elicitations constitute the mechanism of unlearning or are only a link in a chain of events that results in the observed retention losses. We shall return to this question shortly.

Temporal changes in retroactive inhibition: Spontaneous recovery If unlearning has the functional properties of extinction, it should be a partially reversible process. That is, unlearned associations should show spontaneous recovery over time just as do extinguished conditioned responses. This implication was recognized early, and there has been a long history of attempts to find evidence for the recovery of verbal associations.

Absolute increases over time in the recall of first-list associations would constitute direct evidence for recovery if comparable increases do not occur under the control condition. However, since materials acquired in the laboratory are subject to extra-experimental interferences, a decline in the amount of retroactive inhibition, that is, a reduction of the difference between the experimental and control treatment, has been considered as evidence for relative recovery. It should be noted at the outset that it is hazardous to infer the occurrence of recovery in the absence of absolute rises in first-list recall. When relative recovery is found, it is usually because the rate of forgetting is greater for the control than the experimental group. The reason for the convergence of the amounts recalled may lie in the difference between the distributions of associative strengths under the two conditions. On an immediate test of retention the control group is likely to show little forgetting; that is, weak as well as strong items will be recalled. As the retention interval is lengthened, more and more of the relatively weak items may be expected to be lost. The situation is quite different under the experimental treatment, that is, when the immediate test is given after the end of interpolated learning. Only items sufficiently strong to resist retroactive inhibition will be available on the immediate test; subsequent forgetting of such items is likely to be slow. Consequently the changes between an immediate and a delayed test will be smaller for the experimental than the control group (Birnbaum, 1965).

On the basis of the method used to measure retention the relevant experimental studies may be divided into three groups: those using tests of paced anticipation, MFR, and MMFR, respectively. Under conditions of paced anticipation increases in the availability of first-list responses may be offset to an unknown degree by declines in list differentiation and increases in competition effects over time. The MFR procedure eliminates failures of list differentiation as a source of error, but since performance reflects the relative dominance of original and interpolated responses, changes in availability per se cannot be determined. Such changes are presumably measured directly on MMFR tests.

On paced tests of anticipation only small and unreliable increases in first-list recall have been observed (Underwood, 1948a; Briggs, 1954). Absolute rises in the frequency of first-list responses have been obtained on MFR tests; these rises were substantial and significant in one study (Briggs, 1954) but relatively minor and not significant in others (Underwood, 1948b; Briggs, Thompson, & Brogden, 1954). In each case, however, there was a clear convergence in the frequency of first-list and second-list responses as the retention interval was lengthened, indicating decreasing dominance of the latter.

The results of experiments using the MMFR procedure to assess temporal changes in the availability of unlearned associations have been inconsistent. In the bulk of the studies changes in interference were measured after intervals of hours or days. Significant amounts of recovery were reported in two studies (Ceraso & Henderson, 1965; Silverstein, 1967); in both of these the measure of performance was the number of responses recalled regardless of whether or not they were given to the appropriate stimuli. Trends toward absolute recovery which failed to reach statistical significance were obtained in other experiments (Koppenaal, 1963; Ceraso & Henderson, 1966; Slamecka, 1966). In still other cases there was evidence only for relative recovery owing to greater forgetting under the control than the experimental condition (Birnbaum, 1965; Howe, 1967); Houston (1966d) found neither absolute nor relative recovery. In all the studies mentioned so far the *A–B, A–D* paradigm was used. To complete the picture, the results of a study by Saltz and Hamilton (1967) should be mentioned in which a significant amount of recovery was observed for the *A–B, A′–D* paradigm relative to an *A–B, C–D* control condition.

One possible reason for the discrepant findings may be the variation among experiments in the level of retention at the time of the test for spontaneous recovery. Absolute rises in the recall of unlearned associations appear to be associated with high levels of retention under the control condition (see Postman, Stark, & Fraser, 1968, Table 1). The losses of the control groups may be taken to reflect the amounts of extraexperimental forgetting for the materials, degrees of learning, and retention intervals under consideration. The less extraexperimental forgetting there is, the more likely it becomes that absolute rises in recall will be detected, if spontaneous recovery does, indeed, occur. The table referred to above shows that in all cases in which there was at least some evidence of spontaneous recovery the recall scores of the control groups exceeded 90 percent; it is hardly surprising not to find any signs of recovery when the control scores are of the order of 50 or 40 percent (Birnbaum, 1965; Howe, 1967). One method of reducing the amount of extraexperimental forgetting is overlearning of the critical list (Silverstein, 1967). An alternative approach is
Figure 21.26. Temporal changes in interference: mean numbers of first-list and second-list responses (*A–B, A–D*) recalled on an unpaced test as a function of the length of the retention interval. The curve labeled *C* shows the scores of a control group which learned and recalled a single list. Each point represents an independent group of subjects. (Postman, Stark, & Fraser, 1968.)

the measurement of recovery over relatively short retention intervals during which there will be little or no loss under the control condition even after moderate degrees of original learning. A theoretical consideration which favors the use of the latter procedure is that most of the evidence for spontaneous recovery of classically conditioned responses is for intervals measured in minutes rather than days (Kimble, 1961, pp. 284f).

Using retention intervals of the order of 20 minutes, Postman, Stark, and Fraser (1968) obtained reliable evidence for absolute rises in first-list recall. Such recovery was observed when recall of the responses was required. The results of one of these experiments are shown in Figure 21.26. In this series of investigations evidence was also found for systematic temporal changes in performance under conditions of interference. When recall of both the original and the interpolated lists was required, the responses from the most recently learned list were likely to be given first on an immediate test; after a period of delay, however, there was a pronounced shift in the order of recall in favor of the first list. Little evidence of recovery on tests of associative matching was obtained, but since the amount of retroactive inhibition is small to begin with, there is little opportunity for improvement.

Temporal point of interpolated learning To the extent that there is first-list recovery, the amount of retroactive inhibition should vary systematically with the temporal position of the interpolated activity during a given retention interval. The shorter the period between the end of interpolation and test, the less opportunity there should be for recovery to occur. Investigations of the effects on retention of the temporal position of the interpolated activity go back to the beginning of research on retroactive inhibition. The problem derived its initial theoretical significance from the implication of the perseveration hypothesis that retroactive inhibition should decline as the interval between original and interpolated learning is lengthened. Early experiments in which serial lists were used (McGeoch, 1933) did not support this prediction; in fact, relative interference was found to be greater when the interpolated activity occurred immediately before the test of recall rather than directly after the end of original learning. More recent studies in which paired-associate lists were used in an *A–B, A–D* arrangement failed to find an effect of the temporal point of interpolation (Archer & Underwood, 1951; Newton & Wickens, 1956; Houston, 1967c). In the latter study, however, retroactive inhibition did increase with the length of the interval between original and interpolated learning for the *A–B, C–D* paradigm. Newton and Wickens attributed this particular result to the factor of generalized response competition which should be maximal when the interpolated list is learned just before the test of recall.

In the studies considered last, the retention interval was 48 hours or longer. Quite apart from the effects of the interpolation, the retention interval was sufficiently long to produce a substantial amount of extraexperimental forgetting: the recall score of the rest group in the experiment of Newton and Wickens was 64 percent. Thus, it is possible that, as in the studies of recovery discussed above, the effect of the temporal variable is masked by extraexperimental forgetting. The demonstration of a recovery effect should again become more likely when the retention interval is short. In recent experiments by the writer a 20-minute retention interval was used, and interpolated learning took place either immediately after the end of original learning or just prior to the MMFR test. First-list recall was, as expected, found to be higher under the former than under the latter condition.

Extinction versus response suppression What can be said about the success of the extinction analogy in permitting an orderly account of the facts of unlearning? There is

some support, by no means conclusive, for the assumption that the unreinforced elicitation of first-list responses during interpolated practice is a condition of unlearning. However, the apparent high resistance of specific associations to unlearning is damaging to the analogy. It is the responses to individual stimuli that are assumed to be elicited as errors and to undergo extinction, but such specific associations appear to remain largely intact while the responses become less available. It is possible to argue, of course, that contextual associations are extinguished far more rapidly than are specific ones, but there is no clear theoretical reason for such an ad hoc assumption. On the face of it, whatever evidence there is for spontaneous recovery points to a functional similarity of unlearning and extinction. However, when rises in first-list recall do occur, they appear to reflect primarily increases in response availability, and the latter have in turn been found to be correlated with shifts in the order of recall. Taken together, these findings carry a strong suggestion that the mechanism of unlearning operates primarily on the entire repertoire of first-list responses rather than on individual stimulus-response associations.

One possible conclusion is that during interpolated learning a mechanism comes into play which serves to suppress the repertoire of first-list responses and allows the subject to limit himself to the currently prescribed responses. The greater the associative interference entailed by the conditions of transfer the more thorough the suppression of the interfering repertoire will become. From this point of view the elicitation of first-list responses as overt or covert errors does not in itself result in unlearning through a process of extinction but triggers the suppressor mechanism which results in reduced availability of the original responses at the end of interpolated learning. Since it is the response repertoire that is suppressed, specific stimulus-response associations remain for the most part intact; it is only under conditions of heavy and persistent negative transfer, such as under the *A–B, A–Br* paradigm, that individual associations become subject to suppression or perhaps to a process with the characteristics of extinction. On the basis of these assumptions it becomes understandable that unlearning is largely a matter of reduced response availability. Finally, on the reasonable supposition that response suppression is a reversible mechanism the effectiveness of which diminishes over time, increases in response availability on delayed tests of retention may be expected. For a more complete statement of this position see Postman, Stark, and Fraser (1968). It should be apparent that there is a close relation between the conceptions of response suppression and generalized response competition: Suppression of the response repertoire of the first list implies dominance of that of the second list at the time of recall. In that sense the MMFR test may not be free of all effects of competition.

The generality of unlearning The fact that the availability of a repertoire of responses is reduced rapidly during interpolated learning is demonstrated clearly in studies of retroactive inhibition in free recall. When a procedure equivalent to MMFR is used, that is, recall of both the original and the interpolated material is required, substantial decrements in first-list retention are observed. This result has been obtained with lists of nonsense syllables (Asch & Ebenholtz, 1962) as well as in several experiments in which English words were used as the learning materials. In the latter studies retroactive inhibition exhibits functional characteristics that parallel those obtained with paired-associate lists. Thus, the amount of interference is an increasing function of the degree of interpolated practice on a single list (Postman & Keppel, 1967) and of the number of interpolated lists (Tulving & Thornton, 1959). In view of the evidence for the development of higher-order units in free-recall learning (Tulving, 1968), it would not be plausible to attribute the reduced

availability of the first list entirely to the extinction of contextual associations. To the extent that the same conceptual or categorial groupings are used in original and in interpolated learning, the successive lists share common mediating stimuli; with respect to such stimuli the *A–B, A–D* paradigm obtains for individual words (see Shuell & Keppel, 1967; Shuell, 1968). Thus, the conditions believed to be conducive to the suppression of first-list responses are present. As is true in the recall of paired associates, the responses from the second list are likely to be given before those from the first (Asch & Ebenholtz, 1962; Postman & Keppel, 1967).

Significant reduction in the availability of first-list responses has also been observed in the serial-learning situation (Keppel, 1966). Since there is uncertainty about the functional stimulus in serial learning, the nature of the extinctive relation between successive lists cannot be specified with precision. Nevertheless there is an important parallel to the results obtained with paired associates in the fact that losses in response recall are of a substantially larger order of magnitude than in the reconstruction of the serial order of the items. If serial order is a matter of associative chaining, interitem associations again appear to be relatively resistant to unlearning.

PROACTIVE INHIBITION

It is an interesting historical fact that for many years retroactive inhibition was the only condition of interference that received theoretical consideration. Systematic research on proactive inhibition is of relatively recent origin and has developed within a theoretical framework that grew out of the analysis of retroaction. It has become clear, however, that in forgetting outside the laboratory proactive sources of interference probably carry greater weight than do retroactive sources (Underwood, 1957a). Thus, there has been increasing emphasis on the integration of both forms of interference within a common conceptual scheme.

A study by Whitely (1927) provided an early indication that the recall of a test list may be adversely influenced by the activities preceding its acquisition. The phenomenon of proactive inhibition was explicitly identifield and demonstrated in a subsequent investigation by Whitely and Blankenship (1936). In their experiment the test task consisted of a list of monosyllabic words. The material used in prior learning was either another list of words or a series of nonsense syllables. A control group learned only the test list. Recall after 48 hours was significantly poorer under both experimental conditions than under the control condition. There was only slightly less interference when different classes of materials were used in the two lists. It should be noted, however, that subjects served under all conditions in a counterbalanced design and that the retention losses were extremely heavy, so that the experiment was probably not sensitive to the effects of similarity. A second experiment in which stanzas of poetry were used as the learning materials gave comparable results. Whitely and Blankenship interpreted these results as consistent with a transfer theory of interference.

Implications of Transfer Theories of Interference

At this point it will be useful to consider the implications for proactive inhibition of the theoretical analyses of retroactive inhibition. If reproductive inhibition is the only mechanism of interference, retroactive and proactive losses should be equivalent under otherwise comparable conditions, that is, if the retention interval is held constant and the degrees of learning are the same both for the interfering list and the test list. There is no implication in the hypothesis of reproductive inhibition that the effects of specific competition should be asymmetrical, for example, more damaging to the recall of the first than

of the second list. If generalized competition is taken into account, however, there should be less proactive than retroactive inhibition, at least for tests given soon after the end of second-list learning, since the most recently practiced responses are likely to remain dominant at that time. As the degree of dominance diminishes, this difference should become smaller.

The two-factor theory entails the prediction that the retroactive effects will exceed the proactive effects because the first list is subject to both unlearning and competition, whereas the second list is subject only to competition (Melton & von Lackum, 1941). To the extent, however, that unlearned associations recover over time, the advantage of the first list will decline. It must be added that the manifestations of competition may be expected to be influenced by the level of list differentiation at the time of the retention test. Again it is reasonable to suppose that this factor has equivalent effects on the recall of the first and of the second list. This supposition is in general supported by the results of Winograd's (1968) experiments in which differentiation was assessed directly. On the assumption that proactive inhibition is entirely a matter of competition, degree of differentiation may, indeed, become a decisive factor.

These theoretical considerations should be borne in mind as the variables influencing the amount of proactive inhibition are considered.

Degree of Learning

In this section we shall consider the influence on proactive inhibition of variations in the degree of test-list learning and of prior learning. The evaluation of these relations is complicated by the fact that in studies of proaction the test list is the first task for the control subjects, and the second task for the experimental subjects. Thus, there are differences between the experimental and control group in speed of test-list acquisition which depend on the degree of prior learning; moreover, the magnitude of the transfer effects will also vary with the stage of test-list learning. There is some uncertainty, therefore, about the comparability of proactive effects observed under different combinations of prior and test-list learning.

There is little experimental evidence on the relation between the degree of original learning and proactive inhibition. (To make the discussion comparable with that in the section on retroaction, acquisition of the test list will be referred to as original learning.) In one study in which a serial list of nonsense syllables was used as the learning task (Postman & Riley, 1959) the relation was found to be complex, although there was some evidence for increases in absolute interference when very low and very high degrees of original learning were compared.

If competition is the effective source of interference, the amount of proactive inhibition should be some increasing function of the degree of prior learning. The expected relation was found in some studies in which lists of paired adjectives were the learning materials (Underwood, 1949; Atwater, 1953) but in other cases has failed to materialize. (Dallett, 1964; Underwood & Ekstrand, 1966). A somewhat irregular trend in the expected direction has been obtained with serial lists of nonsense syllables (Postman & Riley, 1959). The amount of proactive inhibition has been consistently found to increase with the number of prior lists, both for paired associates (Underwood, 1945) and connected discourse (Slamecka, 1961). In general, the results are in agreement with those for retroactive inhibition, but not nearly as dependable. That is perhaps not surprising, since the effects of competition alone should not be as stable as those of unlearning and competition combined.

Again in agreement with the findings for retroactive inhibition, list differentiation influences the manifestations of competition. Intrusions are most frequent when the de-

grees of original and prior learning are comparable; they decline sharply when the level of practice is substantially higher for the first than the second list (Underwood, 1949). At high degrees of prior learning, therefore, differentiation serves to counteract the effects of competition. It is not certain, however, whether only the ratio of overt to covert intrusions is influenced, or the amount of recall as well.

Similarity Relations

A competition theory of proaction must, of course, predict intertask similarity to be a critical variable. The importance of formal similarity was clearly demonstrated in the study of Melton and von Lackum (1941) in which the materials were serial lists of nonsense syllables. Proactive losses, as measured by recall and relearning, as well as the frequency of interlist intrusions, were substantially greater under conditions of high than of low interlist similarity.

Experiments that permit a separation of the interlist relations between stimuli and between responses have focused primarily on the meaningful similarity of the latter. There are theoretical reasons for expecting proactive inhibition to be an increasing function of response similarity. As we have seen, the hypothesis of parasitic reinforcement assumes that the greater the response similarity the more strength accrues to the first-list associations during the acquisition of the second list. The same is implied by a mediational interpretation. When the second list is learned to a fixed level, therefore, the effective strength of the first list should increase directly with response similarity. However, the expected relation between response similarity and proaction has not been found (Morgan & Underwood, 1950; Young, 1955; Dallett, 1962b, 1964; Postman & Stark, 1964). On the contrary, proactive inhibition at recall typically is greatest when the responses are unrelated (*A–B, A–D*). In some cases at least, the positive transfer effects in the acquisition of the second list are sufficiently great to lead to the overlearning of test-list items which thus become relatively immune to interference (Postman & Stark, 1964). In general, the results of these studies fail to shed light on the mechanisms of proactive interference. The predictions derived from the hypothesis of parasitic reinforcement are not supported. Moreover, response similarity should be conducive to competition and failures of differentiation at recall, but neither retention losses nor intrusion rates bear out this expectation consistently. The possibility remains that on delayed tests of retention interlist response similarity ensures a high level of response recall which serves to offset associative interferences.

Temporal Changes in Interference

Proactive inhibition is by definition some increasing function of time: The difference between the experimental and the control condition is reliably greater on a delayed test than at the end of acquisition. If the processes responsible for the interference are continuous, proactive inhibition should increase progressively as the retention interval is lengthened. This expectation has in general been confirmed (Underwood, 1948a; Greenberg & Underwood, 1950; Slamecka, 1961; Postman, 1962c).

As predicted by the two-factor theory, there is typically less proactive than retroactive inhibition when the retention interval is relatively short. The first confirmation of this prediction was obtained in the experiment by Melton and von Lackum (1941) mentioned earlier, in which serial lists of nonsense syllables were used and the retention interval was 20 minutes. Essentially parallel results were found with lists of paired adjectives by McGeoch and Underwood (1943), but the difference between the two types of interference failed to reach significance. It appears that a clear-cut difference is most likely to be found when negative transfer is relatively heavy (Young, 1955).

Spontaneous recovery of first-list associations should serve to reduce the difference

between the two types of interference. As first-list responses gain in strength, they can compete more and more effectively with those from the second list. Hence there should be not only progressive decreases in retroactive inhibition but also concomitant increases in proactive inhibition. This prediction applies to tests of recall assumed to be subject to specific competition, such as paced anticipation. Convergence over time of the amounts of retroactive and of proactive inhibition has, in fact, been observed under conditions of paced testing (Underwood, 1948a). This convergence occurs, however, primarily because of decreases in second-list recall rather than absolute increases in first-list recall. Thus, a shift in the relative strength of the two response systems is indicated, which is not, however, safely attributable to spontaneous recovery.

On the assumption that MMFR tests are immune to specific competition, the two-factor theory must predict an absence of proactive inhibition on such tests. It is a fact, however, that substantial amounts of proactive inhibition have been observed on MMFR tests in several investigations (Koppenaal, 1963; Ceraso & Henderson, 1965, 1966; Houston, 1967a; Postman, Stark, & Fraser, 1968). In one study (Houston, 1967a), a direct comparison of MMFR and paced anticipation showed the amounts of interference to be equivalent under the two procedures. The retroactive and proactive effects obtained in MMFR converge to the extent that there is less decline for the first than for the second list, or, of course, absolute recovery (see Figure 21.26). Since at least some relative recovery has been usually obtained, convergence is the rule.

The finding that performance on MMFR tests is subject to proactive inhibition poses serious problems of interpretation. On the assumption that specific competition is not operative, the effects of interference between successive response repertoires must be considered. It has already been suggested that the most recently acquired list is dominant on an immediate test of recall but that the degree of dominance diminishes over time. Consequently, the second list loses its initial advantage as the retention interval is lengthened. Moreover, the simultaneous activation of two response systems should have an adverse effect on the recall of both lists as compared to a single-list control condition. Once one of these systems has been aroused at a given point in time, the shift to the alternative system may be impeded sufficiently to depress recall. Such shifts should be facilitated, and the amount of interference be reduced, if the distinctiveness of the alternative response systems can be maintained over time. Thus, if the interference is between response systems rather than specific associations, list differentiation can be seen to remain a critical factor. Such speculations fall short, of course, of specifying the exact conditions responsible for proactive effects observed on MMFR tests. It is important to recognize that this finding cannot be predicted on the basis of current extensions of two-factor theory and that the operative mechanisms are far from being clearly understood.

Cumulative proactive inhibition An important objective of experiments on interference is to examine under controlled conditions some of the variables that are believed to influence forgetting outside the laboratory. Experiments on proactive inhibition are designed to evaluate the influence of prior learning on the retention of recently acquired materials. Prior learning can, of course, be seen as a potential major source of interference outside the laboratory. We turn now to investigations that provide a useful transition between the measurement of proactive inhibition in standard transfer designs and the consideration of extraexperimental sources of forgetting. The findings to be considered concern the effects of prior learning experiences in the laboratory on the retention of newly learned materials. The empirical question here complements that to
Figure 21.27. Recall of serial lists of adjectives as a function of the number of previous lists. Each 12-item list was learned to a criterion of one perfect recitation and recalled 24 hours later. (Data by E. J. Archer, from Underwood, 1957a.)

Figure 21.28. Progressive decreases in recall as a function of stage of practice. Subjects learned lists of 10 paired associates to criterion and recalled them 48 hours later. There were 36 learning-recall cycles. For items of a given degree of learning (*DL*) recall dropped sharply as the number of previous lists increased. (Keppel, Postman, & Zavortink, 1968.)

which studies of learning to learn are directed: Are there systematic changes in recall as a function of the number of prior lists learned and recalled in the laboratory? One might expect on a priori grounds that subjects would learn how to recall just as they learn how to learn. Exactly the opposite turns out to be true: The larger the number of previous lists the subject has learned and recalled in the laboratory, the more rapid is the forgetting of the list learned last. The increases in forgetting become more pronounced as the retention interval is lengthened (Greenberg & Underwood, 1950). These trends develop even though the successive lists are unrelated (*A–B, C–D, E–F,* and so on). The basic finding that retention losses become progressively greater as a function of the stage of practice has been confirmed in a number of investigations, both for paired-associate learning (Warr, 1964; Keppel, Postman, & Zavortink, 1968) and free-recall learning (Wipf & Webb, 1962). The results of still another experiment showing the trends obtained with serial lists of adjectives are shown in Figure 21.27. It is clear that massive amounts of proactive interference are built up even in the absence of formal similarity relations among the lists learned in the laboratory. The conditions of proaction must, therefore, be sought in the interference among the successive response systems acquired within the same experimental situation.

It has been suggested (Warr, 1964) that the progressive declines in retention may reflect not proactive interference but rather the reduction in the number of trials to a fixed criterion that is a consequence of learning to learn. This explanation is, however, untenable in light of the experimental evidence. It is a fact, first of all, that the data fail to show the expected inverse relation between the number of trials to criterion and the amount of retention loss; for example, progressive increases in forgetting are observed even when there is no learning to learn (Underwood & Ekstrand, 1967a). The alternative interpretation is again negated when the probability of recall is compared for items which were given correctly with equal frequency during acquisition but which were learned at different stages of practice. As Figure 21.28 shows, there are drastic decreases in the probability
Figure 21.29. Ebbinghaus' forgetting curve. To obtain the data for this function, Ebbinghaus learned eight lists of 13 nonsense syllables each to a criterion of two perfect recitations during a single session and then relearned these lists to the same criterion after a given interval of time. Retention was measured in terms of the percentage of time saved in relearning as compared with the original learning. (Data from Ebbinghaus, 1885.)

Figure 21.30. The development of cumulative proactive inhibition in the laboratory. The function shows the relation between recall and the number of previous lists learned in the laboratory. Each of the points represents the results of a study in which the subjects served in a number of different conditions, and the critical list was learned to a criterion of one perfect recitation and recalled after 24 hours. (From Underwood, 1957a.)

of delayed recall as a function of stage of practice even when the number of correct responses in learning is held constant.

The fact that proactive inhibition accumulates steadily as a result of prior learning in the laboratory proved to have important implications for much of the experimental literature on forgetting. Until fairly recently it was a standard procedure in studies of learning and retention to use practiced subjects who served under a number of different conditions in a counterbalanced design, often in repeated cycles of the experiment. It was by no means unusual for a subject to learn as many as 20 different lists. (The most famous practiced subject in the history of research on verbal learning is undoubtedly Hermann Ebbinghaus; the number of lists he learned in years of experimentation with himself as the only subject defies a precise count.) The classical experiments agreed in showing massive amounts of forgetting after relatively short intervals. Ebbinghaus' famous curve (Figure 21.29) shows a loss of about 65 percent after 24 hours, and in some subsequent studies forgetting over the same period exceeded 80 percent. It is now clear that proactive inhibition built up as a result of many laboratory sessions is largely responsible for the magnitude of these losses. In an incisive analysis of the experimental literature on retention Underwood (1957a) showed that the amount of forgetting after 24 hours for a list learned in the laboratory declined in an orderly fashion as a function of the number of prior lists learned in the same experiment (Figure 21.30). For the naive subject who learns only one list in the laboratory the retention loss over 24 hours drops to about 20 percent. This analysis provides impressive confirmation for the phenomenon of cumulative proactive inhibition. From a theoretical point of view an important consequence is that the amount of extraexperimental forgetting for which interference theory (or, for that matter, any theory of memory) must account is far less than had been assumed on the basis of the classical studies.

Proactive inhibition and distributed practice Some recent studies of the relation between distribution of practice and pro-

active inhibition have led to a shift in theoretical interpretation away from the extinction-recovery hypothesis to increasing emphasis on the role of the process of differentiation.

For purposes of exhibiting the theoretical considerations that link distribution of practice and proactive inhibition let us consider the acquisition of a list of paired associates under conditions of heavy negative transfer, such as, list *A–E* which was preceded by *A–B, A–C,* and *A–D.* During the learning trials on *A–E* the previous associations to *A* are presumably subject to extinction. If *A–E* is learned under conditions of distributed practice, the extinguished prior associations have an opportunity to recover during the intertrial intervals, and each time they do so they must be re-extinguished. Such successive recoveries will be minimal during the short intertrial intervals under massed practice of the terminal list. The assumption is now introduced that the more frequently the cycles of recovery and re-extinction are repeated, the more complete will be the unlearning of the interfering associations; and the more complete the unlearning the lower will be the level of recovery for the extinguished associations during a subsequent retention interval. It then follows that the delayed recall of *A–E* should be greater when that list is acquired under distributed rather than massed practice because there will be less recovery of prior associations which can become effective sources of competition at recall. Results consistent with this prediction were obtained by Underwood, Keppel, and Schulz (1962), who also concluded that it is the extinction and recovery of contextual associations that are critical for the differences in recall.

That the differences in recall can be impressive indeed was demonstrated by Keppel (1964) in an experiment in which intertrial intervals of 24 hours were used during the acquisition of the terminal list (*A–E*). Eight days after the end of original learning recall of *A–E* was 72 percent when acquisition was under distributed practice, and only 7 percent when it was under massed practice. In a later investigation, however, Keppel (1967) found that the interfering associations (*A–B, A–C, A–D*) are not in fact less available at the time of delayed recall after distributed than after massed practice. This finding is clearly contrary to the central assumption of an interpretation in terms of differential extinction and recovery. On the other hand, the subjects' ability to identify the list membership of responses, particularly of those from the terminal list, was clearly greater under the distributed than under the massed condition. List differentiation is superior because the terminal list is acquired under a temporal schedule different from that for the prior lists. However, while list differentiation may contribute to the facilitation of recall after distributed learning, it probably does not provide the entire explanation because long intertrial intervals continue to have a beneficial effect on retention when only a single list is learned and recalled. Keppel suggests that under conditions of wide distribution the subject has an opportunity to discard associative links that prove ineffective and to select new ones that are more resistant to forgetting.

The evidence points more clearly to a decisive effect of list differentiation when the contrast between massed and distributed practice is introduced in the stage of prior learning. In an experiment by Underwood and Ekstrand (1966) this variable as well as the degree of prior learning was manipulated. The materials were lists of paired adjectives conforming to the *A–B, A–D* paradigm, with *A–D* learning carried to a criterion of one perfect recitation followed by a retention test 24 hours later. There were four degrees of first-list learning, namely, 12, 32, 48, or 80 trials. At each level of prior learning acquisition was either by massed or widely distributed practice. Under the massed condition all trials were given in a single session and were followed immediately by acquisition of the second list. Under the distributed treatment the learning trials were equally spaced over 4 days (3 per day, 8 per day, and so on), and the *A–D* list was learned on the

final day. The degree of prior learning had no significant effect on the retention of the second list. By contrast, the conditions of distribution during prior learning were found to be of major importance. While there was substantial forgetting of the test list when prior learning was massed, the amount of proactive inhibition was minimal when it was distributed. Moreover, an MMFR test showed almost perfect recall of the prior list under the latter condition. It appears, then, that the difference between practice schedules provides a basis for highly accurate list differentiation which serves to reduce drastically the amount of proactive interference. This conclusion is supported by the results of a subsequent study (Underwood & Ekstrand, 1967b) which showed that the beneficial effects of distribution are substantially less when some of the first-list pairs are carried over into the second list. The presence of pairs common to both tasks makes it impossible to differentiate consistently between lists on the basis of the schedule of practice.

The studies discussed last bring to the fore the temporal schedule of practice as a characteristic of verbal tasks on which list differentiation can be based. In earlier analyses of differentiation major emphasis was placed on the relative degrees of learning of the successive lists as a determining factor. It is clear, however, that any feature that permits a valid separation of alternative response systems can serve as an effective basis of differentiation. While the nature of the cues associated with differences in practice schedules has not been specified as yet, it is likely that the "time tags" attached to various tasks do, indeed, play a functional role in differentiation.

INTERFERENCE IN SHORT-TERM MEMORY

In recent discussions of the mechanisms of forgetting interest has centered increasingly on the distinction between short-term and long-term memory. Theoretically, this distinction refers to functionally different processes each of which in turn reflects a different order of events in the nervous system. While there has been a variety of formulations of the dual-process hypothesis (see Melton, 1963a, b; Peterson, 1963), the short-term system is generally viewed as representing the immediate storage of informational input whereas the long-term system provides for relatively permanent storage. The usual assumption is that the short-term store has a limited capacity and that the material in it (the memory trace) is subject to rapid decay. That is, in the absence of rehearsal the trace is assumed to become progressively weaker or less distinct as a function of time. The structural changes that constitute permanent storage are not reversible, and there are no determinate limitations on the capacity of the long-term system.

It is apparent that investigations of these two hypothetical systems call for different experimental operations. The basic concern of studies of short-term memory is with the initial storage of an input or with the fate of the trace representing that input. Hence the procedures in such investigations typically involve a single presentation of stimulus units falling within the subject's span of immediate memory and a test of retention after a brief interval. The memory span is defined by the length of the series (for example, of letters or digits) that can be reproduced without error immediately after presentation; the use of materials falling within the span ensures a sufficiently high level of immediate recall to permit the observation of progressive losses during the period following the presentation. The use of a single presentation reflects the focus on initial storage and on the conditions of retrieval from the short-term store. There is usually no a priori specification of the range of retention intervals that qualifies as "short." There are, however, attempts to infer from empirical data the conditions that limit the operation of short-term memory, such as the number of items that will put an overload on the limited capacity of the system (for example, Atkinson & Shiffrin, 1965; Waugh & Norman, 1965).

In experimental practice, the retention intervals in studies of short-term memory are measured in seconds rather than minutes.

Tests of retention administered after multiple trials of acquisition, or after intervals of minutes rather than seconds, would be normally classified as yielding measures of long-term memory. There are, however, many transitional situations, especially in studies concerned with the relation between the two types of memory processes; in such situations the amount of material may exceed the immediate span, multiple presentations of the materials may be given, and "short" as well as "long" retention intervals may be explored. It is important to note that there are no sharply circumscribed experimental operations that are coordinated with the distinction between short-term and long-term memory, although the practical separation of the procedures is usually not too difficult.

Given the pragmatic usefulness of the distinction between the phenomena of short-term and of long-term memory, there arises the basic theoretical question of whether the evidence does, indeed, support the postulation of separate memory systems or points to a continuity of processes. One approach to this problem has been to test in the context of experiments on short-term memory the principles of interference established in studies of long-term memory.

Methods of Measuring Short-term Retention

Before the question of the continuity of interference processes is considered further, it will be useful to examine in some detail the methods used to measure short-term retention. The most commonly used procedures can be subsumed under two headings, namely, distractor techniques and probe techniques (Murdock, 1967a). We shall discuss each of them in turn.

The distractor technique is characterized by the interpolation of an activity designed to prevent rehearsal between the presentation of the to-be-remembered units and the test of recall. Since the interpolated activity does not involve new learning, the treatment corresponds to the rest condition in experiments on retroaction. When the activity during the retention interval does involve new learning, the treatment becomes equivalent to the experimental condition of the retroaction experiment. Reference experiments illustrating the use of the distractor technique are those of Brown (1958) and of Peterson and Peterson (1959). Some of Brown's results will be considered below; at this point we will summarize the findings of Peterson and Peterson, which have served as a point of departure for many subsequent investigations of short-term memory.

In what must have been, in Melton's words (1963b, p. 8), "a moment of supreme skepticism of laboratory dogma," Peterson and Peterson set out to investigate the course of retention for a single trigram over intervals measured in seconds. The procedure consisted of three stages: first, a trigram was presented auditorily for 1 second; in the next second a three-digit number was announced to the subject who was instructed to count
Figure 21.31. Short-term retention of verbal units. Forgetting curves for a single consonant trigram, a single word, and a triad of words. The retention intervals were filled with a counting task to prevent rehearsal. (Data from Peterson & Peterson, 1959; and Murdock, 1961a.)

backwards from that number by threes or fours; finally after the appropriate interval the signal to recall the trigram was given. Six different retention intervals ranging from 3 to 18 seconds were used.

The results obtained by Peterson and Peterson are shown in Figure 21.31. Retention of the single three-consonant unit declined sharply during the period immediately following presentation and was less than 10 percent after 18 seconds. The figure also displays the findings of a subsequent study by Murdock (1961a) in which the same procedure was used. With a view to determining the effect of response integration on short-term memory, Murdock compared the retention functions for a single trigram, a single monosyllabic word, and a cluster of three monosyllabic words. He replicated the Petersons' findings for a single trigram but found only a small amount of forgetting for a single word; the curves for the trigram and the three-word cluster overlapped closely. These results must be interpreted with caution, however, since it is not certain that the degree of learning for the three types of items was the same, that is, near perfect immediate recall may represent different degrees of overlearning (see Underwood, 1964). It appears that the rate of forgetting may remain the same as long as the number of functional units or "chunks" is held constant. That is, in an unfamiliar trigram each of the three letters is a discrete element, whereas a familiar monosyllabic word functions as one unit. Consequently, a cluster of three words contains as many discrete elements which require integration as does the trigram. The basic findings of the Petersons have been replicated in numerous other experiments, although the forgetting curve often fails to drop as precipitously as that in the original investigation (for example, Melton, 1963b).

When the probe technique is used, a series of items is presented to the subject but recall is tested for only one of these items. At the time of the presentation of the material the subject does not know which item will be called for. The nature of the probe depends, of course, on the composition of the series. When each item in the series is a single unit, such as a digit, the cue at recall is the immediately preceding item: The unit which occupied position $n - 1$ is presented and the subject is required to recall the unit in position n (for example, Waugh & Norman, 1965). When the learning materials are paired associates, one of the pairs is singled out on the test trial; the stimulus term is presented, and the subject has to reproduce the response (for example, Murdock, 1961b; 1963a, b; 1964). A complex variant of the probe technique has been used by Peterson and his associates (for example, Peterson, Saltzman, Hillner, & Land, 1962; Peterson, Wampler, Kirkpatrick, & Saltzman, 1963). Under this procedure several experimental conditions are run concurrently, such that the presentation and test trials of one treatment overlap the retention cycles of other treatments.

The distinguishing characteristics of the probe technique are that the retention interval is filled with the presentation (and sometimes the recall as well) of learning materials but that the subject is uncertain about the item to be recalled next. It is clear that the treatment during the retention interval corresponds to the experimental condition in the design for the measurement of retroactive inhibition. There is every reason to believe, therefore, that the retention scores obtained by the probe technique are influenced by the interpolated activity filling the retention interval, that is, that they reflect varying degrees of retroactive interference. While this fact has been recognized (Murdock, 1961b; Waugh & Norman, 1965), there has also been a persistent tendency to ignore or to minimize the essential equivalence of the operations of the probe technique and of the retroaction experiment. As Keppel (1965) has pointed out, it is clearly not appropriate to treat the distractor and the probe techniques as alternative and interchangeable methods for charting the temporal course of short-term retention. This argument is strongly supported by
Figure 21.32. Comparison of the amounts of forgetting for a single paired associate under the distractor technique (upper curve) and the probe technique (three lower curves). (Keppel, 1965; data from Murdock, 1961b and 1963a; Peterson & Peterson, 1962; Peterson et al., 1962.)

comparisons of the results obtained by the two techniques for comparable materials and retention intervals (Figure 21.32). As would be expected, the retention losses over a given period of time are considerably greater when the interval is filled with the presentation of learning materials rather than a distractor task. It should be noted that in a recent analysis Murdock (1967a) has argued for the essential equivalence of the distractor and probe techniques. In support of his position he leans heavily on the fact that at least for some materials the *shapes* of the retention functions are the same under the two procedures; it would seem, however, that the similarity in the shape of forgetting curves is not a relevant consideration so long as there are significant differences in the amounts retained. It is true that, as he points out, the nature of the interpolated task is not the only variable that determines the retention function; for example, the number of items to be remembered has a significant effect. Recognition of this state of affairs in no way weakens the basic point exhibited in Figure 21.32, namely, that the interpolation of new learning materials during the retention interval can and typically does serve drastically to reduce the level of recall.

The conclusion appears to be inescapable that general inferences about the temporal course of short-term memory, and in particular about the decay of the memory trace, based on data obtained by the probe technique are open to serious question. This is not to imply that the distractor technique necessarily permits a valid assessment of the rate of trace decay. Activities such as backward counting cannot be ruled out on a priori grounds as conditions of retroactive inhibition; the fact that potential sources of interference can never be entirely eliminated has posed an intractable methodological obstacle to tests of the decay hypothesis (see Postman, 1964b). The difference between the distractor and the probe procedures is one of degree and must be considered in light of the known dependence of the amount of retroactive interference on the similarity between the original and the interpolated activity. The important point here is that in many experiments on short-term memory interest has centered on the temporal course of retention under highly complex conditions of interpolation and that the conditions of interference have often neither been systematically manipulated nor adequately analyzed.

Proactive Inhibition

Intraexperimental interference The potential importance of uncontrolled sources of interference in studies of short-term memory is well documented by the evidence for the build-up of proactive inhibition in the course of an experimental session. It is customary in such a session to test each subject repeatedly and under a number of different conditions. Since each test requires only a brief period, the number of successive observations is often quite high. For example, in the study of Peterson and Peterson (1959) subjects were tested eight times at each of six retention intervals. As many as 80 tests per session are by no means atypical. The consequent econ-

omy of experimentation is often cited as an important advantage. In light of the known relation between stage of practice and rate of forgetting in long-term memory (see p. 1107), the question soon arose of whether there was a comparable build-up of proactive inhibition in the short-term situation which might be responsible, wholly or in part, for the observed rapid drops in retention. This possibility was at first discounted because there were no apparent decreases in performance over successive blocks of trials (see Peterson, 1963). Such comparisons do not, however, answer the question since the degree of learning for the test items may increase as a result of practice, so that the positive effects of nonspecific transfer may mask the build-up of interference.

In a study designed explicitly to permit the evaluation of changes in the rate of forgetting as a function of stage of practice Keppel and Underwood (1962b) demonstrated that proactive inhibition does, indeed, develop progressively under the procedures used by Peterson and Peterson. In one of the experiments the to-be-remembered units were again consonant trigrams, and each subject went through six successive test cycles. Retention intervals of 3 seconds and 18 seconds were alternated (3–18–3–18–3–18 or in the reverse order) so that recall could be measured at each stage of practice after both retention intervals. The results (Figure 21.33) show the characteristic interaction of the amount of prior learning with the length of the retention interval. Thus, there are only slight changes in the level of recall on the 3-second tests, whereas the 18-second tests give evidence of a build-up of heavy proactive interference. Note that on the first test retention is perfect after both intervals; this result is in sharp contrast to the 90 percent loss observed after 18 seconds in the Petersons' experiment. It is clear that cumulative proactive inhibition can have a major influence on the level of retention in experiments on short-term memory under conditions of repeated testing (see also Loess, 1964); moreover, as Keppel (1965) has pointed out, the build-up of such interferences may render the experimental observations relatively insensitive to the influence of other variables.

Figure 21.33. Proactive inhibition in the retention of a single verbal unit: proportion of correct recalls as a function of the number of previous items and length of the retention interval. Keppel & Underwood, 1962b.)

A source of bias that may have contributed to the interaction of stage of practice and retention interval in the experiment of Keppel and Underwood was later pointed out by Peterson and Gentile (1965). Since the two retention intervals were alternated, an 18-second test always followed a 3-second test, so that the immediately preceding trigram was retained better and could function more effectively as a source of interference when the test occurred after the longer of the two intervals. In their own experiment Peterson and Gentile were able to demonstrate that the amount of proactive inhibition increases as the interval between successive tests becomes shorter; however, while the magnitude of the retention losses was affected, evidence for the development of proactive effects within a block of test trials was still found when the source of bias was eliminated (see also Peterson & James, 1967). The conclusion that the amount of proactive inhibition which accumulates within a block of trials varies inversely with the intertrial interval was confirmed in an experiment by Loess and Waugh (1967) in which triads of

words rather than trigrams were used as the learning materials. It is possible that differentiation between successive test items is facilitated as the intertrial interval is lengthened.

In all the studies of proactive inhibition discussed so far the distractor technique was used. The evidence concerning the development of intraexperimental interference under the probe technique is less clear. Relevant data were obtained by Murdock (1963a, 1964) whose procedure consisted of a single presentation of a list of paired associates followed by a test of recall for one of the pairs. All positions were tested in the course of a block of trials; under these conditions the length of the retention interval and the number of interpolated pairs are, of course, confounded. The basic data are the functions relating probability of recall to the serial position of the test item. In one experiment (1963a) the results obtained with naive and with experienced subjects were compared, in another (1964) the changes in the retention function over successive stages of practice were investigated. These analyses agree in showing that practice produces a pronounced change in the shape of the retention function. For naive subjects there is both a primacy and a recency effect (that is, the first as well as the last pair in the list has a clear advantage in recall); for practiced subjects there is only a recency effect. Along with the loss in primacy, practice produces an increase in recall for the item occupying the penultimate position in the list; consequently the average probability of recall does not change appreciably. Murdock is inclined to interpret these findings as pointing to a system with a limited capacity for processing information. As practice continues, there is a shift in emphasis away from the initial item to the later ones in the list; however, the amount retained after a constant input remains essentially invariant. It is, of course, possible that changes in the mode of processing information occur as a result of experience. However, a firm conclusion concerning either the development of such changes or the operation of proactive interferences are difficult because the potential determinants of recall under the probe procedure are numerous and complex. There may be changes in degree of learning as a function of practice that are differential for the several positions in the list; for example, recall for the last item is near ceiling from the outset and cannot show improvement, but that is clearly not true for items in the middle positions. The pattern of prior and interpolated items varies for each pair in the list and so does, of course, the retention interval. How the conditions of intralist interference interact with the possible proactive effects of prior lists is not known. It seems necessary to conclude that results obtained by the probe procedure under conditions of multiple testing do not permit a precise assessment of the components of interference.

Formal similarity The question of whether or not interference in short-term memory is influenced by interitem similarity has acquired considerable theoretical significance because of an early assertion that immunity to similarity effects is one of the characteristics distinguishing short-term from long-term processes (Broadbent, 1963). The results of a study by Brown (1958) were consistent with this assumption. Brown first demonstrated that recall for pairs of consonants declined rapidly during a 5-second retention interval filled with the recitation of pairs of numbers; the rate of forgetting increased with the number of to-be-remembered pairs. In a further experiment, in which the same test materials were used, the amounts of retroactive and proactive inhibition were found to be only slightly greater when the interfering items were other pairs of consonants than when they were pairs of numbers. However, the finding that the nature of the interfering material does not influence short-term retention proved atypical.

Using the Petersons' technique, Wickens, Born, and Allen (1963) provided a convincing

demonstration of the fact that short-term recall is subject to proactive inhibition only when the successive test items are drawn from the same class of materials. Two types of materials were used: consonant trigrams and three-place numbers. Proactive interference continued to accumulate, that is, recall declined as a function of the stage of practice, as long as the successive to-be-remembered items came from the same class. However, there was a dramatic "release from proactive inhibition" when an item from the other class was introduced. Thus, there was no evidence of proactive interference with the recall of a trigram on the tenth test trial if the preceding nine items had been numbers; by contrast the interference was extremely heavy when the prior items had been trigrams as well. The trends were parallel when there was a shift from trigrams to numbers.

The results are more complex when the formal similarity of items from the same class is manipulated, for example, when the number of duplicated letters in trigrams is varied. In the experiment of Wickens, Born, and Allen this variable failed to influence the amount of proactive inhibition; the same result was reported by Wright (1967). A detailed analysis of the findings in the latter study showed, however, that letter duplication had dual and opposed effects: the recall of the letters themselves was facilitated but there was interference with the reproduction of the letters in their appropriate positions within the trigrams. Consequently the overall amount of proactive inhibition failed to be influenced significantly by the degree of letter duplication.

Letter duplication represents, of course, only one condition of formal similarity and applies only to units such as trigrams which are composed of multiple elements. There is increasing evidence that in short-term memory a major determinant of interference is the acoustic similarity of the to-be-remembered units and that such interference effectively influences the recall of single letters. The variable of acoustic similarity will, therefore, be considered next.

Acoustic similarity Before proactive effects proper are considered, it is necessary to review briefly some of the findings that have served to establish the significance of the factor of acoustic similarity in short-term memory. The basic reference experiments were carried out by Conrad and his associates. A first step was the demonstration of the fact that letters which are confused in a listening test also tend to be substituted for each other in recall following visual presentation. For purposes of determining the correlation between the two types of errors, Conrad (1964) used a vocabulary of 10 letters comprising two groups of five letters each which had high within-group confusability and low between-group confusability: BCPTV and FMNSX. It will be noted that the vowel sound in the names of the letters is ē in the first group, and ĕ in the second group. Sequences of six letters drawn from this alphabet were presented visually, at a rate of 0.75 second per letter. Each presentation was followed immediately by a written test of ordered recall. A matrix showing the frequency with which these letters were substituted for each other in recall was then constructed. A corresponding matrix of perceptual confusion errors was obtained in a listening test in which the letters were presented for identification against a background of white noise. The two error distributions were found to be highly correlated. Thus, acoustic confusions permit an accurate prediction of the errors in recall after visual presentation. It follows that recall for a sequence of letters should vary inversely with the acoustic similarity of the elements. This prediction was confirmed in an experiment by Conrad and Hull (1964). Two three-letter vocabularies and two nine-letter vocabularies were used, one of high and one of low confusability at each length. Six-letter sequences (including repeated letters) were presented visually for immediate ordered recall. The frequency of

errors was a negatively accelerated increasing function of the probability of acoustic confusion among the letters but essentially independent of the size of the vocabulary, that is, of the information per item.

The conclusion that recall varies inversely with the acoustic similarity of the elements has received repeated confirmation (for example, Wickelgren, 1965a). The errors in recall have been found to be predictable on the basis of an analysis of the distinctive phonemic features of consonants and vowels (Wickelgren, 1965b, 1966a). In his review of recent developments in research on short-term memory Murdock (1967b) points out three significant implications of the studies of acoustic similarity: (1) It has now been established that interitem similarity is an effective variable in short-term memory; (2) the findings support the hypothesis that the representation of items in short-term memory is through a speech or speech-motor code; (3) in view of the systematic relations between distinctive phonemic features and errors in recall it is possible that "forgetting goes on at a more molecular level even than the single item" (p. 428).

There is some evidence that proactive inhibition in short-term recall increases with the degree of acoustic similarity between the interfering and the test items (Wickelgren, 1966b). At this point it is of interest to note that the systematic effects of acoustic similarity on the temporal course of retention have been interpreted as casting doubt on the assumption that short-term memory is subject to proactive inhibition. This argument was developed by Conrad (1967) on the basis of the results of a study in which recall for four-letter sequences was tested after 2.4 and 7.2 seconds. The vocabulary from which the sequences were drawn contained three groups of letters; the elements within groups were acoustically similar, but the confusability between groups was low. The distractor technique was used, the retention intervals being filled with the reading of digits. Recall decreased as the interval was lengthened, and in addition there was a significant shift in the distribution of errors. At the shorter interval there was a significant tendency for errors to be acoustically similar to the correct response, whereas at the longer interval the distribution of letters was more nearly random. Conrad views the findings as supporting a modified hypothesis of trace decay: The pattern of confusions reflects the decreasing discriminability of memory traces as a function of time. Thus, at the shorter interval the traces are distinctive and confusable only with highly similar ones; at the longer interval discriminability has declined sufficiently to permit confusion among the traces of widely dissimilar inputs. Conrad also suggests that in light of the shift in the distribution of errors the retention losses cannot be attributed to proactive inhibition. Similar errors are more frequent after a short than after a long interval, whereas such errors would be expected to be extinguished more thoroughly and to recover more slowly than dissimilar ones. However, as we have seen, it is hazardous to draw firm conclusions about the operation of interference processes on the basis of trends in overt errors.

Semantic similarity The technique used by Wickens, Born, and Allen (1963), namely, a shift in the class of test items, has produced evidence for the effectiveness of semantic similarity as a determinant of proactive interference in short-term memory. Thus, when successive items are drawn from the same conceptual class, there is a build-up of proactive effects; but there is a release from interference when an item from a different conceptual class is introduced (Loess, 1967). The release from interference appears to be contingent upon a shift from a conceptually homogeneous sequence to an item drawn from an entirely new class; when each successive item is drawn from a difficult conceptual class, proactive interference continues to accumulate. It is possible, therefore, that the surprise or arousal produced by the introduc-

tion of an unexpected stimulus may play an essential part in bringing about the differentiation between the prior homogeneous sequence and the new disparate item (Turvey, 1968). In any event, these findings make it clear that semantic similarity can play a significant role in producing proactive inhibition in the short-term situation. This conclusion is also supported by the results of a study by Goggin (1966) who compared short-term retention under the *A–B, A–D* and *A–B, A–B'* paradigms and found proactive inhibition to be less for the latter.

The point that semantic similarity has been shown to be an effective variable in short-term retention deserves emphasis in view of claims to the contrary. Specifically, Baddeley (1964, 1966b) has advanced the hypothesis that semantic similarity is a significant variable only in long-term memory; short-term memory is influenced primarily by acoustic similarity. To test this hypothesis, Baddeley compared the effects of the two types of similarity on short-term recall. Lists of high and of low acoustic similarity (*mad, man, map,* and so on, versus *bar, cow, day,* and so on) were compared, and also lists of high and of low semantic similarity (*broad, great, large,* and so on versus *hot, old, strong,* and so on). As predicted, acoustic similarity had a far greater adverse effect on recall than did semantic similarity; in fact, the influence of the latter was found to be minor. The experimental procedure suffers, however, from a serious flaw that makes it impossible to draw any firm conclusions from the findings, namely, the failure to ensure that the differences in acoustic and in semantic similarity were equivalent in degree. It is far from obvious that the differences in degree of similarity were in fact equivalent, nor is it clear how these differences can be evaluated. Moreover, acoustic similarity is confounded with formal similarity (letter overlap); attempts to untie these two variables (1966b) were only partially successful but nevertheless served substantially to reduce the apparent effect of the acoustic variable. It should be noted that in a long-term situation, in which multiple learning trials were used, these particular manipulations had rather complex and not entirely consistent effects, although it could probably be concluded that both types of similarity were effective (1966a). What remains, then, is some form of interaction between two types of similarity, varied to uncertain degrees, and the number of learning trials. Such evidence does not provide convincing support for inferences about fundamental differences between long-term and short-term memory. We shall return to this problem in the next section.

Retroactive Inhibition

All experiments on short-term memory in which either the distractor or the probe technique is used can be said to be concerned with retroactive inhibition. In order to prevent the memory trace from being maintained or strengthened, it is necessary to interpolate some activity between input and recall. In that sense the experimental operations parallel those in studies of retroactive inhibition. Whether and to what extent the retention losses over brief intervals of time are in fact attributable to retroactive interference is, of course, a basic theoretical issue which cannot be settled on a priori grounds. It is useful, however, to evaluate the effects of the various activities used to fill the retention intervals with reference to the principles of retroactive inhibition in order to determine whether these principles continue to apply in the short-term situation. In many cases a precise evaluation is, however, difficult because the formal design of the retroaction experiment is used relatively rarely by investigators of short-term memory.

Nature of interpolated activity In spite of the complexities of the various probe procedures used, it is clear that interpolated learning produces retroactive inhibition in the short-term situation, and that *A–B, A–D, A–B* still constitutes an appropriate reference paradigm. Results reported by Peterson et al.

(1962, Exp. III) are a case in point. The learning materials were paired associates, with words as stimuli and numbers as responses. For a given pair, the 10-second retention interval was filled with presentations and tests for other pairs. Two conditions are of interest for present purposes, one in which the stimulus of the test item was paired with a new response halfway through the interval (*A–D*) and one in which only new items were interpolated (*C–D*). The probability of recall was substantially lower under the *A–D* than under the *C–D* treatment (.14 versus .27). The same study (Experiment II) also contains evidence for competition effects which undergo systematic changes over time. When the same item was tested twice, with a filled interval intervening between the two tests, there was a tendency for errors on the first test to be replaced by correct responses on the second test. This tendency increased with the length of interval between the tests. As the erroneous response which competed successfully on the first test is forgotten, the correct response can recover (Peterson, 1966b, pp. 195f.). The basic pattern of results, including the changes in the relative strength of competing responses, agrees well with the findings in conventional experiments on retroactive inhibition.

Figure 21.34. Probability of recall of a paired associate after a single presentation as a function of the number of subsequent pairs and length of list. (Murdock, 1963b.)

An essential agreement between the results of short-term and long-term experiments is also indicated when the effects of the amount of interpolated material are considered. In the series of experiments by Murdock (1961b, 1963a, b, 1964), in which recall for a single item was tested after presentation of a list of paired associates, forgetting increased at a negatively accelerated rate as a function of the number of intervening pairs. The asymptote of the retention function decreases with list length (Figure 21.34). While there is little question about the interference produced by the interpolated pairs, the procedure yields inherently ambiguous results since there is a perfect inverse correlation between the numbers of prior and of interpolated pairs; in addition, of course, the retention interval covaries with the number of pairs intervening between presentation and recall. The same interpretative difficulties arise in other studies in which conditions of retroaction and proaction are manipulated concurrently (for example, Wickelgren, 1966b). These limitations on the analytic usefulness of the data obtained by the probe technique have been considered earlier.

Not only the input of new items for learning but also the interpolation of recall trials can serve as an effective condition of interference (Murdock, 1963c; Tulving & Arbuckle, 1963, 1966). The study cited last shows that with the serial position of the to-be-remembered unit held constant, interpolated inputs produce a greater reduction in recall than do interpolated outputs. Both sources of interference come into play in a continuous memory task such as that used by Shepard and Teghtsoonian (1961) to measure temporal changes in recognition. A series of three-digit numbers was presented, with each item occurring twice in the course of the series. New and old numbers followed each other in random order, and the delay between the repetitions of an item was varied. The probability of a correct identification declined
as a function of the number of intervening items. The retention function brings out the extremely great sensitivity of the recognition measure: better than chance identification remained possible after as many as 60 intervening items (see also Shepard & Chang, 1963).

Similarity relations between the original and the interpolated items influence the amount of retroactive inhibition in short-term as well as in long-term retention. The effects are large and dependable when the degree of acoustic similarity between the units in the successive tasks is manipulated. In an experiment by Wickelgren (1965c) the letters in the interpolated sequence were either similar or different in pronunciation to those in the original list; an interfering list comprising the original letters in a new order was also used. Retention of the first list was scored for both the number of items recalled and accuracy of serial position. In item recall the losses were smallest after interpolation of identical items, greatest when the interfering items were similar, and intermediate when they were different. Both identical and similar items interfered more with position recall than did the dissimilar ones. Intrusion errors were predominantly acoustically similar letters. The pattern of findings is consistent with those obtained in long-term retention when other dimensions of similarity are manipulated. Subsequent findings have confirmed the effectiveness of the variable of acoustic similarity in determining the amount of retroactive inhibition in both recall (Posner & Konick, 1966; Wickelgren, 1966b) and recognition (Wickelgren, 1966c).

There is evidence that, over and above formal or acoustic similarity, the difficulty of the interpolated task is a significant factor in short-term retroactive interference. When the interpolated activity consists of the performance of certain prescribed operations, such as adding numbers, classifying numbers as high and low, and so on, the difficulty of the task can be scaled in terms of the amount of information reduced as a result of the operation. Retention is then found to be a steadily decreasing function of the difficulty of the interpolated operation (Posner & Rossman, 1965; Posner & Konick, 1966). A suggested interpretation of these findings is that the interpolated activity interferes with the continued processing (rehearsal) of the original material. Since the subject's capacity is limited, the degree of forgetting will be related directly to the amount of processing time required for the interpolated activity (Posner & Rossman, 1965). In some situations the factors of similarity and difficulty are not readily differentiated. The findings reported by Neimark, Greenhouse, Law, and Weinheimer (1965) are a case in point. When nonsense syllables of low association value were the to-be-remembered units, greater retention losses were produced by the interpolation of other syllables of low association value than of syllables of high or medium association value, or of numbers. These tasks cannot be ordered along a single similarity dimension, and it is possible that the relative difficulty of the materials is a critical factor determining the effectiveness of the interpolated activity.

We return now to the factor of semantic similarity and Baddeley's hypothesis that this variable is effective in long-term but not in short-term memory. Direct support for this hypothesis was claimed in a study by Baddeley and Dale (1966) in which the effect of the semantic similarity of stimulus terms on retroactive inhibition was investigated. The *A–B, A′–D* and *A–B, C–D* paradigms were compared. Stimulus similarity was found to have a significant influence on retroactive inhibition under conditions of conventional list learning but not in a short-term situation in which one presentation of the list of paired associates was followed by a test of recall. The results obtained by the latter procedure were in the expected direction but failed to reach statistical significance. It is fair to say that these results show little more than the limited sensitivity of the short-term technique. While the evaluation

of the results is made difficult by the investigators' failure to hold list length constant in the two situations, a rough comparison can be made between the recall scores for an eight-pair list on the conventional test and a six-pair list on the short-term test. The percentage of items correctly recalled by the control (*C-D*) group was 57 in the conventional situation and 19 in the short-term situation. The corresponding percentages for the experimental (*A'-D*) groups were 38 and 13. Clearly, there are massive differences in the overall level of retention, and the short-term measures lack sensitivity because they are close to the floor of performance. No conclusions about differences between long-term and short-term memory can be drawn from such data. There is an obvious but important methodological point here: A shift from a statistically significant to a nonsignificant effect should not be attributed to a difference in process unless it is reasonably certain that the opportunity to detect a reliable effect has not changed.

The Role of Interference Processes in Short-term Memory

There is substantial evidence that short-term retention is subject to proactive and retroactive inhibition. While there is a dearth of strictly comparable findings, the available results do not point to a basic discontinuity of the principles governing interference in short-term and long-term memory. That is not to say, however, that all short-term forgetting is necessarily the result of interference. Clearly the facts leave open the possibility that there are determinants of retention that come into play only during the period immediately following input. Such a view is espoused in a theoretical analysis by Peterson (1966b) which holds that short-term retention reflects the interaction of a learning mechanism and a recency mechanism. The former is subject to interference, whereas the latter represents the operation of a transitory postperceptual storage process. The relative contribution of the two mechanisms is assumed to vary with the length of the retention interval and the nature of the events filling the interval. The recency mechanism is seen as dominant during the period immediately after presentation but to carry progressively less weight as the retention interval is lengthened.

The assumption of a dual mechanism appears to be supported by the nature of the interaction observed in experiments on short-term memory between the effects of distribution of practice and the length of the retention interval. Specifically, when an item is presented twice, recall is an increasing function of the degree of spacing between the repetitions when the retention interval is relatively long, for example, 8 or 16 seconds; there is a trend in the opposite direction when the interval is very short, for example, 2 or 4 seconds (Peterson, Hillner, & Saltzman, 1962; Peterson et al., 1963). This interaction can be understood on the assumption that the relative weight carried by the postulated component mechanisms changes with the length of the retention interval. As long as the recency mechanism is dominant, spacing will be detrimental; as the learning mechanism assumes increasing importance, the beneficial effects of distribution, which Peterson is inclined to attribute to a consolidation process, can become apparent. As we have seen, there are other possible interpretations of a positive relation between distribution of practice and retention. However that may be, it would be an error to claim that all the empirical facts of short-term memory can be readily subsumed under existing principles of interference. On the other hand, there is little question about the effectiveness of interference processes in the short as well as the long term.

Reminiscence The fine-grain analysis of short-term retention functions has served to revive interest in the phenomenon of reminiscence which has had a long and checkered

experimental history. Reminiscence refers to an increase in retention with time which occurs in the absence of formal practice. That is, reminiscence represents a reversal of the usual declining trend of the retention curve over time. Before the recent findings in experiments on short-term memory are mentioned, a few words should be said about earlier results in studies of long-term memory.

The occurrence of reminiscence was first reported in the recall of poetry by children after a period of days (Ballard, 1913; Williams, 1926). In these investigations the same subjects were tested both immediately after the end of learning and after a period of delay. Later work (Ammons & Irion, 1954) has shown that under these conditions the apparent rise in the retention curve is an artifact attributable to the practice effects of the immediate test. In studies of verbal rote learning, in which this difficulty was avoided by the use of single retention tests, reminiscence was found after intervals of the order of 1–2 minutes, typically after massed practice on a serial list (Ward, 1937; Hovland, 1938). The increase in performance was most commonly ascribed to the decline of inhibitory influences during the retention interval, such as the dissipation of reactive inhibition or the forgetting of relatively weak interfering associations. However, attempts to reproduce the phenomenon have in many cases proved unsuccessful (for example, Underwood, 1957b), and the exact combination of conditions required for the occurrence of reminiscence have resisted identification.

It should be noted that in some recent studies (for example, Kleinsmith & Kaplan, 1963, 1964) substantial reminiscence over a one-week interval was reported for materials which produce a state of high emotional arousal at the time of learning. The investigators suggested that the traces of such stimuli are initially characterized by a high level of neural activity which renders them relatively inaccessible but which favors consolidation. Consequently, immediate recall is low but is followed by reminiscence after an interval of delay. By contrast, materials that produce a low degree of arousal have an advantage in immediate recall, but on the delayed tests forgetting rather than reminiscence is found. Presumably a low level of neural activity is conducive to early accessibility of the traces but is unfavorable to consolidation, and hence to long-term retention. If these speculations prove tenable, the conditions of reminiscence in these experiments are clearly quite different from those in the classical studies of rote learning.

What appears to be reliable evidence for reminiscence has been obtained in two recent experiments on short-term memory in which the distractor technique was used. In a study by Peterson (1966a) lists of five paired associates were presented once and recalled after intervals ranging from 0 to 24 seconds. While the form of the retention functions varied with the serial position of the item during presentation, the characteristic trend was for recall to decrease at first and then to increase. Short-term reminiscence after a single presentation of a list of five paired associates was also observed by Keppel and Underwood (1967) who measured recall after intervals ranging from 4 to 304 seconds. The peak of the retention function occurred at 19 seconds after presentation. In a theoretical discussion Peterson (1966b) attributes the initial retention losses to failures of the short-term mechanism, and the subsequent gains to increases in the effectiveness of an associative mechanism. One possibility is that interference from relatively weak competitors diminishes with time, so that recall of the correct association becomes more probable. The assumption that there is rapid forgetting of interfering associations, which is also discussed by Keppel and Underwood, represents a return to one of the classical theories of reminiscence. It now appears that short-term tests after a single exposure are more sensitive than earlier procedures to temporal changes in the relative strength of correct and

incorrect associations. In any event, reminiscence, which was once aptly described as a "now-you-see-it-now-you-don't phenomenon" (Buxton, 1943, p. 337), is again becoming visible in the context of short-term memory.

SINGLE-LIST RETENTION

In this final section we shall consider some of the conditions that determine the forgetting of a single list learned in the laboratory. The losses which are observed after a retention interval must be attributed to extra-experimental influences because they occur in the absence of formal manipulations of either prior or intervening activities. Whether or not such losses reflect retroactive and proactive *interference* from sources outside the laboratory is, of course, a central issue in the theoretical analysis of forgetting. An interference theory of forgetting answers this question in the affirmative: It holds that the principles of retroaction and proaction established in controlled experiments specify the necessary and sufficient conditions of forgetting outside the laboratory as well. Such an assertion may be designated a Strong Law of Interference. A Weak Law of Interference would recognize retroactive and proactive inhibition as sufficient but not as necessary conditions of forgetting.

The strong form of the interference hypothesis was formulated in a classical paper by McGeoch (1932a) in the context of a refutation of the law of disuse (Thorndike, 1914) according to which an association that fails to be exercised grows progressively weaker over time. McGeoch based his rejection of the law of disuse largely on the evidence that the amount forgotten during a fixed interval of time is significantly influenced by the nature of the activities intervening between learning and recall. (At that time retroactive inhibition was the only condition of interference that had been studied intensively; the phenomenon of proactive inhibition remained to be pursued.) Among the results he cited were comparisons of retention
Figure 21.35. Recall after intervals of sleep and of waking. The values shown are the average scores of two subjects who served under all conditions of the experiment. (Data from Jenkins & Dallenbach, 1924.)

after equal intervals of sleep and waking. Such comparisons provide a useful transition from the formal experiment on retroaction to the assessment of extraexperimental sources of interference. A period of sleep is essentially free of activity and hence should produce less interference with the retention of previously learned materials than an equivalent period of normal waking activity.

The Effect of Sleep on Retention

A classical reference experiment on the effect of sleep on retention was that by Jenkins and Dallenbach (1924). The two students who served as subjects in this extended investigation learned lists of 10 nonsense syllables to a criterion of one perfect recitation and were tested for recall either 1, 2, 4, or 8 hours later. The retention interval was spent either in sleep or in normal daytime activity. The results are shown in Figure 21.35. While there was forgetting under both conditions, recall was consistently higher after an interpolated period of sleep than of waking, and this difference increased with the length of the retention interval. Sleep does not, of

course, set in all at once, so that an increasing separation between the two treatments would have to be expected. Note that under the sleep condition there are no losses between 2 and 8 hours. The basic finding that sleep reduces forgetting was confirmed in a similar study by van Ormer (1932), who attempted to take account of the effects of diurnal variation on performance and measured retention by the method of relearning. The two retention functions diverged more gradually than in the earlier study, which may in part be a function of the difference between the methods of measurement used. The results were seen as clearly contrary to the law of disuse and consistent with an explanation of forgetting in terms of interference. However, the possibility that sleep favors the process of consolidation could not be ruled out.

In both these early studies each subject served repeatedly under all treatment combinations and hence learned a large number of lists (486 lists in van Ormer's study). Consequently, there is no doubt but that massive amounts of proactive inhibition accumulated in the course of the experiment. The question was, therefore, raised by Ekstrand (1967) of whether a period of sleep facilitated retention in the classical studies by reducing proactive rather than retroactive inhibition. Using naive subjects, and paired words as the learning materials, Ekstrand measured retention after an 8-hour interval. Recall was again significantly higher when the interval was spent in sleep rather than waking (84.6 vs. 73.3 percent). Thus, the positive effect of sleep is not contingent upon interference from prior lists learned in the laboratory. In a further experiment Ekstrand evaluated the effect of sleep on retention under manipulated conditions of interference (*A–B, A–D*). Performance on an MMFR test after an 8-hour interval showed that sleep facilitated recall of both the first and the second list. This effect was substantially greater in first-list recall; in fact, there was absolute recovery of the first list after a period of sleep but not after a period of wakefulness. The occurrence of absolute recovery argues against the hypothesis that sleep favors consolidation, since the trace of *A–B* must be assumed to have been disrupted during the acquisition of *A–D*. As was noted earlier, (p. 1099), recovery is most likely to be observed when the overall level of retention remains high, as after a period of sleep.

There is clear evidence, then, that sleep during the period following acquisition facilitates retention. This fact is contrary to the principle of disuse and points to retroactive interference produced by the subject's normal waking activities as a condition of forgetting. The specific sources of interference that result in forgetting, and their mode of action, are left open. As it turned out, the systematic analysis of the latter problem focused on proactive rather than on retroactive effects. Interest came to center on proactive sources of interference for two major reasons. First, since the individual's language habits are the most likely source of interference in the forgetting of verbal materials, proactive effects should carry far greater weight than retroactive ones. That is, the language habits acquired and practiced throughout an individual's lifetime should exert a more potent influence than his particular verbal activities during a limited retention interval. The second reason is closely related to the first. The individual's language habits, which are assumed to constitute the sources of proactive interference, can be specified more fully and more precisely than his uncontrolled verbal activities between the end of learning and the delayed test of recall.

Degree of Learning and Retention

Problems of measurement Before we consider the evidence bearing on the mechanisms of interference in single-list retention, a methodological digression is required, namely, a discussion of some interpretative problems that arise in the measurement of long-term retention. Our point of departure is the fact that amount of retention is an increasing function of the degree of original

learning. The relation is a strong and dependable one, and it applies not only to the levels of acquisition up to the attainment of a criterion of perfect recitation but to degrees of overlearning as well (Kruger, 1929; Postman, 1962d, Underwood & Keppel, 1963). As a consequence of this fact, complex problems of measurement and interpretation develop whenever one wishes to evaluate the effects on retention per se of a variable that influences the speed of original learning. Examples are provided by investigations that are designed to determine whether slow learners forget more than fast learners, or whether materials of high meaningfulness are retained better than materials of low meaningfulness. If a constant number of learning trials is given, the terminal levels of acquisition will differ substantially for fast and slow learners and for easy and hard materials; thus, the amounts of retention cannot be compared directly. The apparent solution of carrying acquisition to a fixed criterion of performance unfortunately leaves the measures of retention subject to systematic biases.

The source of the difficulty is that the level of performance to be expected following the attainment of a fixed criterion actually depends on the speed of acquisition. Consequently, the predicted levels of immediate retention will likewise depend on the speed with which the criterion is approached. Two factors are responsible for this relation. First, as noted earlier, the attainment of a criterion represents a chance peak in performance and is likely to be followed by a drop on the next trial (the criterion fall); the slower the rate of acquisition, the larger the criterion fall will be. Second, the final acquisition trial on which the criterion is attained provides an opportunity for additional learning; the faster the learning rate, the greater is the resulting increment in associative strength. This fact is apparent in Figure 21.36, which shows growth curves of associative strength for fast and for slow learners. It is clear that each correct response (reinforcement) produces a greater increment in associative strength for the former than for the latter. That will be true on the trial on which the criterion is reached and on overlearning trials as well if practice is continued beyond the point of perfect performance. In sum, the criterion fall will be smaller, and the amount learned on the criterion trial will be greater, for fast than for slow learners; the predicted retention scores differ correspondingly. If the observed scores are compared directly without reference to expected values, there will be a relative underestimation of the amount forgotten by fast learners, or conversely, a relative overestimation of the losses of the slow learners. Exactly the same considerations apply, of course, when retention is compared for materials which are acquired at different rates, such as lists of high and of low meaningfulness.

Figure 21.36. Curves of associative growth. The probability of a correct response on a succeeding trial increases as a function of the number of correct anticipations (reinforcements) on the preceding trials. The curve rises more rapidly with the number of reinforcements for fast than for slow learners. (Underwood, 1954.)

The analysis of the logic of measurement in studies of retention is due largely to Underwood who has also taken the lead in developing and evaluating solutions to the difficulties outlined above (Underwood, 1954a, 1964, 1966; Underwood & Keppel, 1962). There are

three methods which have been used to reduce biases in measures of retention which result from differences in degree of original learning. First, tests given immediately after the end of acquisition to independent control groups will provide empirical estimates of the expected retention scores for the groups differing in speed of learning. Subjects tested after a period of delay are then compared with the control subjects to determine the amount of retention loss. Second, the expected retention scores are estimated by extrapolation from the curves of associative growth, by a technique known as successive probability analysis. Specifically, the function is determined relating the probability of a correct response to the number of reinforcements (prior correct responses) during acquisition. On the basis of this function a recall probability can be assigned to each item learned by a given subject; the sum of the probabilities constitutes the subject's predicted retention score. The difference between the predicted and the obtained score provides a measure of forgetting. The interpretation of the measures obtained by both the techniques described so far is, however, subject to an important limitation. If the predicted levels of retention are not the same, and the group with the lower expected score shows a greater amount of forgetting, it remains uncertain whether this result is attributable to the difference in degree of original learning or to the operation of the independent variable under investigation (for example, meaningfulness). That is, quite apart from a possible effect of the independent variable, the rate of forgetting may vary inversely with the degree of original learning. This interpretative problem is avoided if one makes sure that the expected retention scores are in fact approximately equal for the groups to be compared. The third available procedure, designed to meet this objective, consists of adjusting the numbers of learning trials given to the experimental groups so as to equalize as closely as possible the expected retention scores. The appropriate adjustment must, of course, be first determined in a pilot investigation. Thus, one may find that 5 trials on a list of high meaningfulness and 10 trials on a list of low meaningfulness will yield about the same predicted retention scores. In addition, probability analysis can be used to check on the accuracy of the adjustment and to take account of remaining minor differences in degree of learning. It should be noted in conclusion, however, that all three procedures cease to be applicable if original learning is carried beyond the point at which the associations to be recalled have reached asymptotic strength. There is no known technique for predicting in advance the effects of overlearning on the retention of a given type of material.

Retention as a Function of Degree of Learning and Intralist Similarity

The importance of the problems of measurement we have been considering may be illustrated with reference to the relation between intralist similarity and retention. This topic is directly relevant to this section because the theoretical interest in investigations of this relation centers on a possible mechanism of interference in long-term retention. Let us refer back at this point to Gibson's application of the principles of generalization and differentiation to the phenomena of verbal learning (pp. 1048–1052). The point of departure of the hypothesis is that the acquisition of a verbal list requires the reduction of generalization tendencies among the stimulus terms, that is, that learning requires stimulus differentiation. It is assumed further that differentiation decreases over time, leading to spontaneous recovery of the generalization tendencies. The higher the degree of intralist generalization during acquisition the greater will be the recovery and hence the retention loss. It follows that the amount of forgetting should increase as a function of intralist similarity.

Gibson (1942) reported the results of an experiment that appeared to give some sup-

port to this deduction from the theory. The learning materials were lists of paired associates composed of geometric forms as stimuli and nonsense syllables as responses; the degree of generalization among stimulus forms was either high or low. The speed of learning to a criterion of one perfect recitation was far greater for the low-generalization than for the high-generalization lists. However, after 24 hours recall was somewhat higher for the low-generalization list. Although the difference was not statistically reliable, Gibson attached importance to it and considered it as consistent with theoretical expectations in view of the greater opportunities for overlearning in the acquisition of the high-generalization lists. It is now clear that such an interpretation is not tenable. As was indicated above, the more gradual the approach to criterion the lower the expected retention score is likely to be. It cannot be assumed, as was suggested by the investigator, that the overlearning of some items in the more difficult list outweighs this relation. Given large differences in speed of acquisition, raw differences in recall scores simply cannot be interpreted. This study was considered in some detail because it exemplifies a fairly common situation: the observation of a difference in recall that is theoretically important but of an order of magnitude which could be produced by inequalities in the degree of original learning.

Subsequent studies in which both the formal and the meaningful similarity of the stimulus terms in paired-associate lists were varied (for example, Underwood, 1953a, b; Beecroft, 1956) have failed to support the theory. When degree of learning is constant, the expected inverse relation between stimulus similarity and retention does not materialize. In fact, trends in the opposite direction have been observed (Joinson & Runquist, 1968). The reasons for the failure of the prediction, which is plausible on both theoretical and common-sense grounds, are not clear.

It is possible that a high degree of intralist similarity reduces the susceptibility of the materials to extraexperimental interference. In a high-similarity list the stimuli are drawn from a limited repertoire: a small number of letters is used when the items are nonsense units, or a circumscribed domain of meanings is represented when they are words. Consequently, as intralist similarity increases, there is a reciprocal restriction in the range of extraexperimental experiences which are closely enough related to become effective sources of interference. This reciprocal relation between intralist and extralist interference becomes clearly apparent when successive lists, all at a constant level of similarity, are learned in the laboratory (Underwood, 1954b). Another factor, which may be important but which is difficult to evaluate, is that the subject learning a high-similarity list is forced to develop especially effective ways of differentiating among the stimuli; as a result, the associations that are established may be very resistant to interference from extralist sources (see Dallett, 1966; Battig, 1968, pp. 165f.). Put another way, at the end of acquisition the level of similarity among the stimulus terms may be functionally less than it was initially, and it is the terminal level which may be critical for the subsequent course of retention.

Extraexperimental Sources of Interference

We now turn to recent systematic applications of principles of interference to extraexperimental forgetting. The basic fact that requires explanation first of all is the retention loss shown by a naive subject for a single list learned in the laboratory—of the order of 20 percent after 24 hours. This loss occurs in the absence of formal manipulations of either prior or intervening activities, and according to the Strong Law of Interference it must be attributed to retroactive and proactive inhibition from extraexperimental sources.

Sources and mechanisms of extraexperimental interference In the forgetting of verbal materials the extraexperimental sources of interference must be sought in the sub-

ject's language habits and in his verbal activities prior to and following the acquisition of the experimental task. An attempt to specify some of these sources and their possible mode of operation was made in a theoretical analysis by Underwood and Postman (1960). The major points were as follows:

1. It is assumed that the mechanisms of retroactive and proactive inhibition, as established in the laboratory, are operative in extraexperimental forgetting as well. Greater weight is assigned to proactive than to retroactive effects (see p. 1123).

2. The conditions of interference from extraexperimental language habits conform to the *A–B, A–D* paradigm, where *A–B* is a pre-existing linguistic association and *A–D* is the association prescribed in the experimental situation. The acquisition of the new sequence *A–D* requires the unlearning or inhibition of the prior habit *A–B*. However, *A–B*, which is assumed to represent a strong and stable language habit, will recover over time and interfere with the subsequent recall of *A–D*. Moreover, if *A–B* is practiced after the end of the experiment, the retroactive effects of such practice will summate with the proactive ones to enhance the amount of interference at recall.

3. Two classes of language habits (*A–B*) which are likely to become effective sources of interference are identified: (a) letter-sequence habits and (b) unit-sequence habits. Letter-sequence habits reflect the sequential probabilities of letters in the language. For example, TH and QU are highly probable sequences, whereas TJ and QZ are highly improbable ones. Interference increases as the linguistic probability of the letter sequences in the learning task diminishes. Thus, the degree of letter-sequence interference describes a gradient, declining progressively as the prescribed sequences approximate more and more those occurring most frequently in the language. An alternative statement of this principle is that the more thoroughly integrated a verbal unit is, the less susceptible it is to letter-sequence interference.

Unit-sequence habits represent associations established through linguistic usage between integrated units such as words. They become a source of interference to the extent that these pre-existing associations are of higher strength than those prescribed in the learning task. The more frequently a word occurs in the language, the larger should be the number of other words associatively connected with it (see Noble, 1952 and Chapter 19); hence the number of potentially interfering associations elicited by a word should be an increasing function of the frequency with which it occurs in the language. These considerations lead to the postulation of a gradient of unit-sequence interference. This gradient reflects the assumed inverse relation between word frequency and degree of interference. It should also be noted that the amount of unit-sequence interference is expected to be maximized when pre-experimentally associated words occur within the same list but occupy non-adjacent positions in the sequence to be learned. In such a case the situation is analogous to that in the *A–B, A–Br* paradigm: interfering responses cannot be inhibited because they are correct elsewhere in the list.

Empirical tests The above analysis can be seen to entail two predictions: (1) the more probable a sequence of letters is in the language the better it should be retained, and (2) the retention of a sequence of words should be related inversely to the frequency of usage of the units of which it is composed. A substantial number of studies designed to test these predictions has been carried out. In general the results have failed to support the theory. When the degree of learning is controlled, the most likely finding is that the amount of retention loss is the same for various types of materials. There have been some exceptions, but only a few of these are in accord with theoretical expectations; others add to the evidence calling for modification of the original analysis.

In most of the studies designed to evaluate the effects of letter-sequence and unit-
Figure 21.37. An experimental test of the hypothesis of letter-sequence interference. Retention after 1 and 7 days of lists of letter pairs when the associative connection between the stimulus and the response letter was high (*HA*) and when it was low (*LA*). Comparisons are made after amounts of practice on each list which yielded the same expected retention score on an immediate (3-sec) test. (Underwood & Keppel, 1963.)

sequence interference on retention there were multiple acquisition trials, and recall was tested after intervals of days. A few representative studies will serve to illustrate the largely negative findings. To assess the influence of letter-sequence interference, Underwood and Keppel (1963) used lists of paired associates composed of single-letter stimuli and single-letter responses. The initial associative strength between the paired letters, as determined from normative tables, was either low or high. There were six different degrees of learning, ranging from 2 to 25 anticipation trials; retention was tested after either 1 day or 7 days. As expected, the speed of acquisition was considerably greater when the degree of associative connection between the letters was high than when it was low. However, when the retention losses for the two lists were evaluated after equivalent degrees of original learning, no consistent differences were found (Figure 21.37). This finding is clearly contrary to the hypothesis of letter-sequence interference.

Figure 21.38. An experimental test of the hypothesis of unit-sequence interference: retention curves for lists of words of high and of low frequency of usage. (Postman, 1961b.)

Figure 21.38 presents the results of an experiment (Postman, 1961b) in which unit-sequence interference in the retention of serial lists of words was investigated. Lists composed of nouns of either high or low frequency of usage were compared. In the retention of serial lists there should be interference not only from extralist habits but also from associations among nonadjacent items. Interference from both these sources should be greater for the high-frequency than the low-frequency lists. Original learning was to a criterion of one perfect recitation; retention was tested after intervals of 30 seconds (control), 2 days, and 7 days. The high-frequency lists were learned significantly faster than the low-frequency lists, and this difference in rate of acquisition is reflected on the immediate test. The amounts retained are, however, essentially the same. The curves do cross after seven days, but the difference in the rate of forgetting is far from significant. The expected inverse relation between word frequency and retention also failed to materialize in studies of paired-associate learning (Postman, 1962e) and free-recall learning (Ekstrand & Underwood, 1965).

It is interesting to note that more rapid forgetting for high-frequency than for low-frequency words was observed by Turnage (1967) in a short-term memory experiment in

which the Petersons' technique (see p. 1110) was used and the retention intervals ranged from 2 to 30 seconds. It is possible that unit-sequence interference is effective only after very low degrees of practice (see also Turnage & Anderson, 1965). The fact that the predicted differences are typically observed early in list acquisition is consistent with this possibility. If so, the trends observed in the short-term situation cannot be used to explain long-term losses after multiple-trial learning.

When the conditions of prior learning are manipulated in the laboratory, the results again fail to show the expected effects of unit-sequence interference. The theoretical expectation is that proactive inhibition will be greater when the successive lists learned in the laboratory are composed of high-frequency rather than low-frequency words. This prediction follows from the fact that there are more interitem associations among high-frequency than among low-frequency words; hence, there should be more interlist interference at recall for materials of high than of low frequency. However, the predicted difference in the amount of proactive inhibition has not been found, for either serial lists (Postman, 1962c) or paired-associate lists (Underwood & Ekstrand, 1967a). Thus, formal experiments on proactive inhibition confirm the negative results obtained in studies of single-list retention.

The virtually uniform lack of evidence for the predicted effects of extraexperimental sources of interference poses a troublesome puzzle because it appears to imply a basic discontinuity between the conditions of forgetting manipulated in the laboratory and those which come into play during a retention interval outside the laboratory. For this reason there has been a continuing effort to identify possible shortcomings in theoretical formulations and experimental procedures that may be responsible for the empirical failures. These analyses have been concerned primarily with the role of unit-sequence habits in retention. One approach has been to re-examine the potential role of such h in long-term retention, and in particul give consideration to sources of facilitation. Another approach has been to develop empirical tests of the basic assumption that the procedures used to study retroactive and proactive inhibition in the laboratory are representative of the conditions of extra-experimental interference. Some illustrative examples of these lines of attack on the shortcomings of current conceptions of extraexperimental interference will now be given.

It has been suggested (Postman, 1963) that interference theory is apt to predict too much forgetting because it fails to take adequate account of the sources of facilitation that serve to reduce the amount of forgetting produced by such mechanisms as unlearning and competition at recall. The prediction of an inverse relation between word frequency and recall is a case in point. This prediction was based on the fact that high-frequency words have more associative connections than do low-frequency words. The higher the word frequency, therefore, the greater is the number of potentially interfering associations which must be inhibited during acquisition and which may recover or be relearned during the retention interval. These considerations focus on the conditions determining the amount of associative loss; performance on a test of recall will, however, also depend on the availability of the responses. Now it is a fact that the existence of multiple interitem associations, which is characteristic of a sample of high-frequency words, facilitates free recall (Deese, 1959, 1960), that is, has a pronounced positive effect on the availability of the items when the list can be reproduced without regard to serial order. The interitem associations impose what Deese (1962) has called external associative structure on the list and reduce the range of alternative responses. The situation here parallels that discussed earlier with respect to the reciprocal relation between intralist and interlist similarity. It follows that a high

degree of interitem association may be expected to have dual and opposed effects on retention: It will enhance not only unit-sequence interference but also the availability of responses. The relative weight of these components will depend not only on the requirements of the retention test, that is, whether or not items must be reproduced in serial order, but also on the length of the retention interval. Conditions determining response availability should become increasingly important as the interval is lengthened.

The following experiment (Postman, 1967) provides evidence for systematic changes over time in the balance of positive and negative effects of pre-experimental interitem associations. The learning materials were serial lists of familiar English words. There were two types of lists distinguished by the degree of interitem associative strength. The high-strength lists consisted of items that were closely interrelated: The words in a list were all normative associates of a common stimulus and also tended to elicit each other as free associates. There were no known associative relations among the words in the zero-strength lists. Learning to criterion was by the method of serial anticipation, and retention was tested by recall and relearning either 30 seconds or 7 days later. Contrary to the results in free recall, the high-strength lists were learned somewhat more slowly than the zero-strength lists. As Figure 21.39 shows, the latter have an advantage on the immediate test of recall, as would be expected on the basis of their more rapid acquisition. However, on the delayed test there is a substantial difference in favor of the high-strength lists. This difference is not maintained as relearning progresses; rather the curves cross and the zero-strength lists regain the superiority found in acquisition and on the immediate test. Re-exposure to the list restores response recall under both conditions, and the differences in unit-sequence interference once more become apparent. The large difference in recall and the rapid reversal in relearning may be regarded as rather direct evidence for the dual and opposed effects of interitem associations. For other evidence regarding the role of response availability in delayed recall see Postman, Fraser, and Burns (1968), and Underwood and Ekstrand (1968a). It would be inappropriate to conclude, of course, that previous failures to observe differences in retention expected on the basis of the unit-sequence hypothesis can be attributed to a near balance of positive and negative effects. The point is rather that the experimental analysis of long-term retention must seek to specify extraexperimental sources of facilitation as well as of interference.

Figure 21.39. Recall and relearning of serial lists of high (*H*) and zero (*Z*) interitem associative strength 30 sec and 48 hr after the end of learning. The score on the first relearning trial provides a measure of recall. (Postman, 1967.)

We now turn to the question of whether the experimental manipulations in conven-

tional laboratory studies of retroactive and proactive inhibition are in principle representative of the conditions of extraexperimental interference. In considering this question, Underwood and Ekstrand (1966) pointed to two potentially important differences between the conditions of interference which are created experimentally and those which may be presumed to come into play outside the laboratory. First, extraexperimental associations are likely to be of much higher strength than interfering associations established in the laboratory. Second, linguistic associations are acquired and used under conditions of distributed practice, that is, varying intervals of time intervene between one occasion of use and the next. By contrast, the acquisition of interfering associations in the laboratory is typically massed, being carried out entirely within a relatively brief experimental period. In an experiment on proactive inhibition described earlier (p. 1108), Underwood and Ekstrand (1966) attempted to assess the probable effects on retention of these quantitative differences between linguistic and experimentally established associations. The major findings were that degree of prior learning had relatively minor effects on retention but that there was a drastic reduction in the amount of proactive inhibition when the interfering lists were learned under distributed rather than massed practice. As was pointed out, the temporal schedule of practice may have provided an effective basis of differentiation between the test task and the prior lists. Accurate differentiation between prior language habits and experimental associations should be possible on the same basis since acquisition is widely distributed for the former and massed for the latter. Again interference theory would appear to predict too much forgetting, in this case because of a critical quantitative difference, namely, with respect to the degree of distribution of practice, between experimentally established and extraexperimental associations.

While some of the shortcomings of existing theoretical formulations and ex[perimental] procedures are beginning to be [un]derstood, they do not offer a satisfactory explanation of the stubborn empirical fact that with only rare exceptions the amount retained is independent of the nature of the material, as long as the degree of learning is held constant. It is possible that in some cases positive and negative effects counteract each other, but it would be a weak theory indeed which would account for a basic invariance in retention in terms of a precise balance between facilitation and interference. As Underwood and Ekstrand put it, "Until we are able to identify the source or sources of interference producing the constant forgetting in the naive subject the decay theorist has some grounds for glee" (1966, p. 548). The glee should, however, be only moderate since the decay theorist finds himself in the same boat as the interference theorist: the one must aver that the rate of decay remains the same for all kinds of traces as long as the degree of learning is constant, the other that the amount of interference remains the same.

It is important to recognize the difficulties which the apparent invariance in the amount of retention for different types of materials poses for theories of forgetting and to avoid question-begging solutions. Consider, for example, the explanation proposed by Adams (1967) for the empirical failures of the hypothesis of extraexperimental interference. He suggests that the expected differences fail to materialize because the subjects' use of "natural language mediators" renders various types of materials equally resistant to interference. Such mediators are described as "self-imposed" (p. 87) and appear to include any kind of mnemonic or coding device developed during acquisition. In discussing the study of letter-sequence interference by Underwood and Keppel (see p. 1128 above), Adams suggests that natural language mediators may have been formed with equal frequency for the probable and for the improbable letter pairs and that as a

consequence there was no difference in retention (p. 195). But how plausible is such an explanation in view of the fact that the learning of the probable pairs was far more rapid than that of the improbable ones? Surely the drastic difference in speed of learning has some implications for the availability and stability of "natural language mediators." It is precisely the fact that the difficulty of acquisition appears to be largely unrelated to the amount of subsequent retention which poses the critical theoretical problem. Whether or not one is inclined to place emphasis on the usefulness of mediators and mnemonics, the finding which requires explanation is that a roughly constant proportion of the originally acquired associations is likely to be lost over a given period of time. So far the factors responsible for these losses have not been adequately specified. The application of experimentally based laws to forgetting outside the laboratory promises to be an arduous task.

SUBJECT INDEX

Å
  Ångstrom = 10^{-10} m = 0.1 nm
"ABBA" order," 5
AC/A
  near-focus response measurement
    accommodation, 384
av
  association value
    meaning, 852–858
Absolute limen (threshold), RL, 14–16, 50
  audition, 233–235, 239–242, 555
  binocular vision, 296
  light-and-dark adaptation, 284–285, 287–289, 296
  olfaction, 201–202, 203–207, 210–211
  pain, 155, 157–158
  reinforcing brain stimulation, 648–649
  taste, 175–177, 186, 188–189
  temperature, 143–148, 149–150
  touch, 133–134, 135–136, 137
  vibratory sense, 135–136, 137
  vision, 377
  visual acuity, 298, 303, 304, 306–307
Accommodation
  convergence, 477–480, 481, 482, 484, 491, 493, 499, 502, 511–513
  depth perception cue, 477–480, 493, 513
  eye movement, 383–384, 393, 441
  intra-ocular muscles, 391, 478
  near-focus response, AC/A, 383–384
  reaction time, RT, 391–392
  reading, 393–394
  threshold, 479
  visual focus, 391
Acquired drive
  *secondary (acquired) drive, 709, 717–719, 802–811
Acquired stimulus distinctiveness
  observing response hypothesis, 782–783
  paradigm, 782
  transfer, 780–783

*An asterisk is a suggestion to "See" or "See also."

Acquired stimulus equivalence
  paradigm, 782, 1073, 1076
  transfer, 780–783, 1073, 1075
Activation
  *arousal, 831–845
Activation theory, 831–832, 837
Activity
  *general activity, 657, 673, 804, 808, 821–826
  *instrumental activity, 797, 808, 812, 813, 826–831
Acuity
  visual acuity, 298–306
Adaptation
  adaptive continuum, 744–748
  cue adaptation, in CL, 948
  definition confusions, 184–185
  definition in olfaction, 210
  delay of reinforcement, 684
  deprivation schedules, 817–821
  electric shock, 723–724
  neural, 108
  punishment, 737
  recovery in olfaction, 210
  response decrements, 588, 590, 592
Adaptation, perceptual
  distorted vision, 541–543
  figural aftereffects, 465–474
  hue, 415
  left-right reversal, 541
  rearranged vision, 533–540, 543–546, 549
  tilt, 539–540
Adaptation, sensory
  color, 334–338, 348, 367–368
  color vision, 415
  effect on reinforcement, 627
  light-and-dark adaptation, 283–289
  olfaction, 210–212, 213
  olfactory cross-adaptation, 214–215
  pain, 158–160
  pupil, 392
  selective chromatic, 341–344
  taste, 171, 183–186, 188

Adaptation, sensory (*cont.*)
taste cross-adaptation, 186
temperature sense, 142-145
touch, 129, 131, 132, 136
Adaptation level, 765
Helson, 412, 416-417, 434
Helson theory, 59, 637
Adjustment, method of
psychophysical methods, 14, 20-23
Affectivity
emotionality of words, 857-858, 863-865, 900
Aftereffects
curved lines, 542-543
figural aftereffects, 465-474
movement aftereffects, 521-522, 545
optical rearrangement, 534, 542, 545, 549
Afterimage
Emmert's law, 473, 511, 512
eye movement recording, 371, 376, 380
icon, in shape perception, 444
light-and-dark adaptation, 288-289
size perception, 511
tonal, 244
All-or-none law
potential, 100
All-or-none learning theory
*cue-selection model, 949-960, 982
empirical basis, 986-987
learning curve derivation, 986, 991
All-or-none model, PAL
axioms, 990, 1002
evaluation of, 993-994
*Markov chain, 990-993
one-element model, 990-994, 1001-1002, 1005-1006
parameter c (probability of learning), 990-992, 994
stationarity, 992
statistics of the model, 991-992
Alleyway
*maze learning, 573, 576, 602, 618-621, 631-634, 639-640, 663, 667, 673, 695-696, 720-722, 724,
Alternation
*probability learning, PL, 937
Alychne
colorimetry, 356
Anchor points
*serial position effect, 1016-1017
Ångstrom
Å = 10^{-10} m = 0.1 nm, 89
Animal psychophysics
*comparative psychophysics, 753-757
Anticipation
anticipatory errors method, 1013-1015
error in psychophysics, 15
method, in PAL, 855, 980-981, 1006, 1035-1037
paced anticipation method, 1098-1099, 1105
of reinforcement, 809-810
serial anticipation learning, 853-854, 885-886, 893-894, 896, 897, 980-981
warning signal, 720
Anticipatory response
conditioned, 564, 621, 805-806, 810
delay of reinforcement, 680
*drive theories, 801
incentive motivation, 622, 695, 805
measurement, 621-622
reinforcement, 621-622
Anxiety
*conditioned emotional response, CER, 707, 712-717
discrimination learning, 789-791
generalized, 733
manifest anxiety scale, 790-791
*motivation
Aperture color
Arousal
behavioral, 823, 838
behavioral vs. EEG, 844
concept of, 831
discrimination learning, 841
*drive, 658-659, 794-830, 840-841
electrical brain stimulation, ESB, 658-659, 839, 841-843
electroencephalogram, EEG, 591
exploratory behavior, 839-841
frustrative nonreinforcement, 837
general energizer concept, 796, 833-834, 843-845
heart rate, 829, 834-836, 840, 843-844
measurement, 831-834
novel stimulation, 834
optimal level hypothesis, 832, 840-841
perceptual deprivation, 840-841
physiological indicants, 832-840, 843
vs. reinforcement, in ESB, 811
reticular formation, 832
in secondary reinforcement, 663, 673
sleep-wakefulness continuum, 831-832
stimulus intensity effects, 839-841
threshold, 823
Articulation (intelligibility)
speech, 223, 254-259
Association
vs. concept formation, 945, 954
consummatory response, 816-821
discrimination learning, 770-771, 777
effective associative strength, 770-771
laws, 569, 849, 881-882, 884, 885, 1122, 1123
vs. selection process, in CL, 949
span, 715, 729
*word association
Associationism, theory of, 569, 848-850, 975, 980
Associative learning
verbal learning stage, 858-859, 892-893, 1059, 1066-1067
Attention
attention pretraining, 781-782
attentional response, 948
auditory variable, 232-233
differential, in color perception, 421
discrimination learning, 757, 769-772
selective, 1001
selectivity, in speech, 258-259
serial position effect, 1016
Audition
attention variable, 232-233
backward masking, 241
beats, 237, 239
clicks, 233, 241
cochlear microphonic, 230
cochlear nucleus, 230-231
detectability threshold, 233-234, 239-242, 250, 555
diplacusis, 244
distortion, 237-239, 256

low tone, 262-263, 265, 266
median plane, 259-267
phase, 242, 261-262
place theory, 265
reverberation, 269
time cues, 260-263, 264, 267, 268-269
time-intensity trade, 262-263, 265, 266

Auditory space perception
bat, 223, 269-270
blind people, 223, 270-271
echo-ranging systems, 269
porpoise, 223, 270
sonar systems, 269

Auditory stimulus
sound, 223-227

Averaged response curve
*learning curve, 599-600, 609, 612, 916-918, 929, 986

Aversive behavior
acquired aversiveness, 677
*avoidance behavior, 707-708, 725-733
classical conditioning, 707-711, 740
*conditioned fear, 709-720
*electric shock, 704-741
electrical brain stimulation, ESB, 647, 651, 658, 675, 692
*escape behavior, 617, 707-708, 720-725
extinction, 708
general theory, 740-741
instrumental (operant) training, 707-709, 740
nondifferential reinforcement, 708
noxious stimulus, 703-709
partial punishment, 708
preservation procedure, 707-708
pseudoconditioning, 560, 577-579, 717, 729-730, 803-804
*punishment, 707-708, 733-739
response noncontingency, 692
response-contingent shock, 707-709
*secondary (acquired) drive, 709, 717-719, 802-804
sensitization, 560, 577-579, 737
shock onset, 707-708, 719
shock termination, 707-708

Aversive stimulation
*noxious stimulus, 557, 560, 568, 569, 703-741

Avoidance
tastes, 190-191

Avoidance behavior
acquisition, 726-728
acquisition failures, 730
active avoidance, 733
*aversive behavior, 707, 740
classical conditioning, 727-729
conditioned emotional response, CER, 716-717, 726-727
*conditioned fear, 726-728, 732
definition, 707, 725
determinants, 728-730
differential inhibition, 717
drug effects, 730, 732
electrical brain stimulation, ESB, 658
and escape, 727
extinction, 727, 732
heart rate, 726
insoluble discrimination, 791
instrumental (operant) training, 726, 727
nondiscriminative, 730-732
passive avoidance, 733
procedures, 708, 725-726, 728
pseudoconditioning, 717, 729-730
reinforcement, 727-728
response-shock (R-S) interval, 730-731
reticular formation stimulation, 843
secondary (acquired) drive, 803
shock-shock (S-S) interval, 730-731
shuttle box apparatus
Sidman avoidance, 724-727, 730-732
theories, 568, 726, 727, 740-741
warning signal, 725-729

Avoidance conditioning
temperature sense, 149-150

Background effects
color, 343, 367-368, 393, 402, 416-417
contrast, 397, 413-414

Backward learning curve
*learning curve, 612-613

Behavior
anatomical substrate, 88-92, 102-103
definition, 595
verbal-behavioral distinction, 944-945

Behavioral baselines, 600-601, 642, 677, 686

Behavioral contrast
discrimination learning, 777-779
frustration, 641
reinforcement, 641-642

Behaviorism, 2, 562, 621

Bezold-Brücke hue shift
color, 348

Binocular vision
absolute limen (threshold), RL, 296
accommodation threshold, 479
averaging, 488
color mixture, 487
contours, 483, 486-489
coordination, 381-384, 389
depth perception, 463, 480-494
disparity, 310, 381, 383, 423, 481-485, 489, 491-494, 502
Fechner's paradox, 488
fixation, 381-382
fusion, 481, 487-489, 491-492
fusional vergence, 383, 393
mosaic composition, 487-488
neural pathways, 283
Panum's area, 488
prevalence, 297
Pulfrich pendulum effect, 309-310
rivalry, 487-488, 491
space, 492-494
stereoscopic vision, 482-494
summation, 296-297, 487-488
suppression, 488, 489, 491-492

Biological need
vs drive, 797, 799, 800

Blank trial
concept learning, CL, 959-960
probability learning, PL, 932-933
reinforce-test procedure, 987-989
Blindness
auditory space perception, 223, 270-271
Blue-arc phenomenon
vision, 285
Body temperature
deprivation effects, 824
lateral hypothalamic regulation, 647
*temperature sense
Brain
activation pattern, 831-832, 837
chronic electrodes, 599
control of feeding, 651-652, 798
cortical associative areas, vision, 283
electrical brain stimulation, ESB, 113-114, 599-600, 617, 642-660, 674-675, 691-692
electrophysiology 94, 113-114, 115
hippocampal activity, 837-838
intracellular recording, 92

FORMULAS USEFUL IN LABORATORY WORK

Length

1 meter (m) = 3.28 feet (ft) = 39.37 inches (in.)
= 100 centimeters (cm) = 1000 millimeters (mm)
= 10^6 micrometers (μm), or microns (μ)
= 10^9 nanometers (nm), or millimicrons (mμ)
= 10^{10} Ångstrom units (Å)
1 foot = 12 in. = 30.48 cm
1 inch = 2.54 cm

Volume

1 liter (l) = 1.0567 quarts (qt) = 1000 milliliters (ml)
= 1000.03 cubic centimeters (cc or cm^3)

Weight

1 gram (g) = .0022 pound (lb) = .035274 ounce (oz)
= 1000 milligrams (mg) = 10^6 micrograms (μg)

Angle

1 degree (°, deg) = 60 minutes (min) = 3600 seconds (sec) = 0.0175 radian (rad)

Photometry

1 millilambert (mL) = 0.929 footlambert (ft L) = 3.183 candles per square meter (c/m^2)
= 10 apostilbs

Frequency

1 cycle per sec = 1 cps = 1 Hz = 360°/sec = 2 π rad/sec

Time

1 second (sec) = 1000 milliseconds (msec) = 10^6 microseconds (μsec)

Temperature

Degrees centigrade (°C) = 5/9(n°F − 32) = n°K − 273
Degrees fahrenheit (°F) = 9/5n°C + 32
Degrees kelvin (°K) = n°C + 273

$\pi = 3.1416$

$e = 2.71828$
